vations he established the important fact that it was only in gray mosquitoes that had fed on birds in whose blood the Proteosoma parasite was present that those pigmented bodies occurred. (7) From this Ross correctly inferred that the pigmented body was an evolutionary form of Proteosoma. (8) MacCullum had previously shown that in the case of the analogous parasite—the Halteridium—the flagellum, of the flagellated phase, after breaking away, entered certain spherical, pigmented Halteridia, causing them to be transformed into little travelling pigmented vermicules, which, in virtue of their sharp beak and mechanical power, traversed freely red and white corpuscles. (9) Analogy suggested that a similar thing occurred in Proteosoma, and that the travelling pigmented Proteosoma vermicule entered the tissue of the mosquito's stomach and became Ross' pigmented body, in the same way as Manson had shown took place in the case of the Filaria sanguinis hominis. (10) Arrived in the stomach wall of the mosquito, the Proteosoma increased rapidly in size until it projected beyond the stomach walls into the cœlom, or body cavity, of the mosquito, as a rounded body, which he styled the Proteosoma coccidia. (11) During its progress and growth various changes took place in size and in the appearance of the contents of the coccidia. Pigment diminished and then disappeared, and as the parasite protruded into the cœlom it was seen that the contents had a more or less granular appearance. (12) The coccidia now burst, and what Ross called germinal vermicules, which had formed in its interior, were set free in the body, blood, and tissues of the mosquito. (13) The next step in the problem was one of great consequence—it was no other than the discovery of these vermicules in the venomo-salivary glands of the mosquito. Ross during dissection of the mosquito found a couple of head glands with a duct leading toward the proboscis of the animal, and traced the parasite vermicules into these glands. (14) The climax of the discovery was now within Ross' grasp, and he elucidated it thus: He allowed mosquitoes to feed on birds infected with Proteosoma; after a few days he fed the mosquitoes on birds whose blood was void of any parasite infection. He found in due course that the parasite-bearing mosquitoes had infected the healthy birds and that the blood of the latter was charged with Proteosoma.

Thus was the cycle completed, and the analogy between bird and human infection had only to be proved to establish what was no doubt a great scientific truth, that the mosquito was a carrier of malaria and an infecter of man. Much had yet to be done, however, before the full significance of the mosquito in malaria was worked out. Malaria, it was known, multiplied without the intermediary of any vertebrate. Did it do so solely in mosquitoes? If so, we had yet to learn how it passed from mosquito to mosquito. Did it multiply in other media? If so, what were they? Dr. Manson said that he had given merely the outline of Ross' great work. Doubtless Ross or others would soon take up the other problems it suggested and show how to solve them. It was impossible in a short space to give in detail the multitudinous experiments and observations he had carried out. Suffice it to say that they had been done in a masterly way and with a power of reasoning, of induction, and of technical detail which marked Ross as one of the most eminent scientific workers of the day. The practical applications of the discovery were immeasurable, and the fact that as the bites of the snake or the rabid dog inoculated the blood of their victims, so might the mosquito convey malaria, opened up a new and hopeful phase in the prevention of disease in the tropics.

Dr. Andrew Davidson put a resolution, which was unanimously carried, that the section send a message of congratulation to Surg.-Maj. Ronald Ross, of the Indian medical service, for the excellent work he had done in connection with researches into the subject of malaria and the rôle the mosquito played in its spread.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Third Day—Friday, July 29th.

Symphyseotomy.—Dr. Buist, of Dundee, read a paper entitled "Two Symphyseotomies." His own experience was that operation in the patient's own house, while much more troublesome for the surgeon, did not act prejudicially to the patient. In his first case there had been three previous pregnancies, the first two resulting in stillbirth, and the third had been terminated by the induction of premature labor with subsequent death of the child. Pelvic measurement, diagonal conjugate, 9 cm. He adopted Frank's method of operation. The patient recovered and the child, which was born alive, died later from bronchitis. The second case was that of a rachitic woman, primipara. Diagonal conjugate, 10 cm. She was first seen when she had been two full days in labor. Symphyseotomy was done by the subcutaneous method, puncture being made below the clitoris. Forceps were applied. Both mother and child recovered. The competing methods were craniotomy and the induction of premature labor.

Dr. Morisani, of Naples, discussed the paper in French. He said that he obtained a separation of 7 cm. between the bones, which increased the available conjugate by 2 cm. He discountenanced premature labor, and thought that the children of such labors often grew up to wish that they had never been born.

Dr. John Moir, of Edinburgh, in answer to the remarks of the last speaker, stated that several of the children of the patients upon whom he had induced labor had lived to become worthy citizens and fathers of families.

Treatment of Cystocele.—Dr. Amand Routh, of London, read a paper on the treatment of cystocele by a new operation. He said that cystoceles might be divided into primary and secondary. The former was sometimes produced in the first stage of labor when, owing to premature rupture of the membranes, the cervix was carried down and urine might collect, acutely distending the lower part of the bladder. In this form pessaries were of no use. Anterior colporrhaphy was not satisfactory and gave no permanent relief, unless at the operation the bladder was stripped off the anterior vaginal wall and the anterior wall of the cervix; he made an incision in front of the cervix as for anterior colpotomy, and then a vertical incision through the length of the anterior vaginal wall. He made a semilunar flap on each side of this incision, and after removing all redundant tissue he put in stitches vertically and transversely, fixing the uterus. When elongation of the cervix existed, he amputated, after ligating the base of each broad ligament.

Dr. Sanger, of Leipsic, made a vertical incision over the cystocele with a semilunar flap on each side of this, and used a continuous suture. He also did a colpoperineorrhaphy at the same time, splitting the perineum as far as the anus, and carrying the sutures up the posterior vaginal wall to the cervix.

Dr. Fehling, of Halle, thought that the chief point in the treatment of cystocele was to put the uterus in good position by either ventral or vaginal fixation.

Dr. Giles, of London, recognized two forms of cystocele—the first when the uterus was low down; the second when the uterus was in good position, but there was elongation of the anterior vaginal wall. In the second form the indication was to diminish the size of the vaginal wall, but in the first this only did harm by bringing down the cervix and fixing it in wrong

position. The speaker thought that the second form was caused in labor by the driving down of the anterior vaginal wall and the loosening of its attachment to the pubes. He suggested the possibility of restoring the connections of the anterior vaginal wall and pubes; failing that, he would advise ventral fixation.

Dr. Martin, of Berlin, thoroughly agreed with Dr. Fehling as to the importance of beginning with the treatment of any defect in the uterus that might be present, especially the putting of the uterus in a good position. We must always avoid applying sutures to the uterus, in doing vaginal fixation, at a higher level than two centimetres above the internal os.

Dr. Lapthorn Smith, of Montreal, thought it was useless to do colporrhaphy without at the same time fixing the uterus. He performed the following series of operations at one sitting: Curetting the uterus, vaginal fixation, amputation of the cervix, anterior colporrhaphy, posterior colporrhaphy, and perineorrhaphy.

Vaginal Extirpation of Uterine Fibroids.—Dr. Smyly, of Dublin, read a paper on the extirpation of myomatous uteri by the vagina, in which he said that this operation was mainly due to the labors of Péan and Doyen. He had performed the operation seventeen times. He could not indorse the opinion that "fibroids kill as surely as, though more slowly than, cancer." The conditions which in his opinion called for operation were pressure symptoms, sloughing, pain, hemorrhage, inability of the patient to work, and rapid growth of the tumor. In the case of small tumors, vaginal was better than abdominal hysterectomy. As regards myomectomy, when the tumors were multiple, nodules which were left behind might still grow. Polypi were exceptional in this respect, and if these appeared they could easily be removed. He made it a rule when hemorrhage was a prominent symptom to dilate the cervix and remove any prominent submucous growths; even if this did not cure, hysterectomy could be done later. As regards oöphorectomy, it might be difficult or impossible, and even when performed it did not always arrest growth of tumor; he preferred vaginal hysterectomy by Doyen's method, by which he had removed tumors up to five pounds in weight. One case of this series had terminated fatally. In all cases he had done Doyen's morcellation, using clamps for the broad ligaments, and the conclusions he had arrived at were that this operation was better than removal of the appendages, and that nervous symptoms were less severe after removal of the uterus and ovaries than after removal of the ovaries only.

Dr. Landau, of Berlin, said that one should bear in mind the danger of a myoma degenerating into a sarcoma; also the danger of necrosis. He had observed several times more growth and pain after the menopause, and he urged the importance of not delaying until the heart had been affected by the hemorrhage.

Dr. Smyly, in reply, said that the greatest difficulty in cases of myoma was to decide whether any operation was necessary, and in that way they differed entirely from cases of ovarian tumor.

Dilatation of the Os Uteri.—Dr. Farrar, of Gainsborough, read a paper entitled "A New and Speedy Method of Dilating a Rigid Os in Parturition." This consisted in applying tampons of a ten-per-cent. solution of cocaine to the os.

Dr. Jardine, of Glasgow, had tried cocaine pessaries for the same purpose, but had come to the conclusion that they did no good.

Dr. Alice Ker, of Liverpool, had found injections of hot water very useful for rigid os; also that they diminished the severity of the pains.

Dr. Donald, of Manchester, read a paper on "Vaginal Section." He had performed fifty-nine operations, with a mortality of 6.5 per cent.

Conservative Surgery of the Ovary.—Mr. Christopher Martin, of Birmingham, read a paper entitled "Conservative Surgery of the Ovary." He said that the physiological value of the ovaries was shown by the results which followed their complete removal. In his opinion it was unjustifiable to remove both ovaries in cases of cystoma unless the tumor was sarcomatous, in which case both ovaries should be removed even when only one was affected; in inflammatory disease he would leave one ovary whenever possible. He would perform resection of the ovary for fibroma, dermoid, and cystic disease, leaving the healthy part of the ovary. In chronic cystic ovaritis he would perform ignipuncture. In parovarian and broad-ligament cysts he would enucleate and leave the ovary. In hysterectomy, vaginal or abdominal, he would leave one or both ovaries.

SECTION OF MEDICINE.

First Day—Wednesday, July 27th.

The President's Address.—Dr. George W. Balfour, of Edinburgh, delivered the president's address, taking as his subject "A Personal Experience of an Almost Forgotten Episode in Medical History." There were not many now alive, he said, who could remember the time when bloodletting was the panacea for almost every ailment, and when, if patients could be no longer safely bled, they were certainly leeched or cupped. There must be few survivors of the time when one was taught that in uncomplicated pneumonia the only essential action of the prognosis was the day of the disease on which the treatment by venesection was commenced, as it sometimes failed when delayed more than two or three days from the commencement of the disease. Yet such were the earliest lessons in medicine which the speaker had received in the wards of the old Royal Infirmary.

When within a year of graduation he made his way to Vienna with the view of investigating homœopathy, he studied percussion and auscultation under the world-renowned Dr. Joseph Skoda, and his astonishment was great when he found that the severest cases of pneumonia were treated with poultices and regulated doses of extractum graminis (hay tea), and with nothing else unless much pain was complained of, when a few grains of Dover's powder were added. It was astonishing to see a pneumonia melting away under the magic influence of the decillionth of a grain of phosphorus, but it was indeed a *reductio ad absurdum* to find this same magic influence exerted by hay tea, and to be told by Skoda that pneumonia was a disease which tended not to dissolution but to resolution.

The *ἰσχὺς πάθους* of Hippocrates was raised to a paramount position by Hahnemann, who enunciated the doctrine that by it alone could disease be not only cured, *tuto, cito, et jucunde*, but silently and at once extinguished. In this respect homœopathy was the eighteenth century analogue of our modern antitoxin treatment. Remedies were selected not for any healing virtues they were supposed to possess, but because of the power they were believed to have of exciting a disease similar to that they were supposed to cure. For one fresh from a school where it was taught that "in the case of inflammation no one would think of trusting the safety of the patient to any other remedy than bloodletting," it was a sufficiently startling experience to observe patients with true sthenic pneumonia not only treated by drugs in infinitesimal doses, but making excellent recoveries under their use. Naturally the first and most obvious idea was that there really must be some occult virtue developed by the various triturations and succussions, and some truth in the homœopathic aphorism, *similia similibus curantur*. But the excellent results obtained by Skoda with his hay tea sufficed to dispel this idea, while the success

of Dietl in the same class of cases in another hospital with simple aqua colorata showed that there was nothing specific even in hay tea, and but confirmed the unmistakable conclusion that, as Skoda put it, pneumonia tended not to dissolution but to resolution, and that the large bloodlettings thought necessary for its treatment were, to say the least, uncalled for.

Though in the Edinburgh school much stress continued to be laid upon the necessity for bloodletting, it had ceased to be carried to such an extreme as in the immediately preceding generation. Dr. Balfour was once told by an old gentleman that he heard Professor Gregory in a clinical lecture boast that he had bled a man into convulsions, adding that the students had rushed terror stricken from the ward, and that he himself had been disconcerted for a moment. The patient recovered. In a series of MS. clinical lectures still extant, Gregory narrates the still more remarkable case of Betsy Moffat, who during an attack of pneumonia had suffered much from bloodletting, tartar emetic, and other perturbative treatment; at last she was found insensible, her pulse 104 and feeble, and a rattle in her throat like one dying. Even Gregory admitted she could not be further bled, but by dint of stimulating her with hartshorn and sack whey he was able to apply a few leeches to her head, and before he left the ward he was able to take four more ounces of blood from her arm, blood which, as Gregory tells us, was still buffed and cupped. Incredible as it might seem, this patient did not die, but on the contrary was able to be discharged exactly one week after her last bloodletting. Gregory was a very able man and no fool: he quite recognized the danger of large bloodlettings, especially in weakly patients. But while he considered the remedy unsafe, he thought it less dangerous than the disease, and in this opinion he was supported by the pathology of his day.

On his return from Vienna, Dr. Balfour read before the Medico-Chirurgical Society of Edinburgh a report of what he had observed in the wards of Skoda, with an account of 392 cases of pneumonia, treated on what might be termed the expectant principle, and showing a mortality of only 54, or 1 in 7¼, equal to 13.7 per cent. He pointed out that the Vienna cases were certainly not less sthenic than those in Edinburgh, that they had the disadvantage of being daily unceremoniously auscultated, percussed, and lectured over, and that they had not the advantage of having been freely bled, yet their mortality was only 13.7 per cent. The mortality in the Edinburgh Infirmary was at that time 35.9 per cent. But his words fell on deaf ears, and the conclusion arrived at was summed up in the words of Dr. John Gairdner, who said that nothing was better established in Edinburgh than the good effect of bloodletting, whatever might be the case in Vienna, and that if Dr. Balfour or any one else could shake his conviction in the truth of this opinion, he would also succeed in producing in his mind a general distrust of medical evidence in all cases of every description, since in no case whatever could we have evidence which is stronger or more satisfactory.

The eclectic treatment of pneumonia, however, passed gradually into the hands of the general practitioner, and within less than ten years the late Professor Bennett wrote: "It is admitted that the practice of bleeding in acute inflammations has, within a recent period, undergone a great change; that whereas it was formerly the rule to bleed early, largely, and often repeatedly, now such bleeding is rarely practised, and is not necessary."

If at the end of the last century the profession generally had been fully alive to the fact that since the days of Pythagoras—a contemporary of Hippocrates—there had never been wanting a body of eclectic physicians, many of them the most renowned physicians of their day, who shunned perturbative medicine and guided their patients safely through the most acute diseases without having recourse to any so-called heroic practices, it seemed unlikely that even the skilful special pleading of Cullen would have sufficed to establish bloodletting as a treatment upon a foundation apparently so stable. And in the absence of the factitious contrast between the action of heroic medicine and that of infinitesimals, it seemed equally unlikely that Hahnemann's ideas as to the preparation and powers of infinitesimals would have taken any hold on the profession.

We were now on the threshold of new discoveries and of quite a new pathology, which was indeed but a higher development of ideas that had long been slumbering in the professional mind—the connecting links being Dwight, Raspail, Hallier, and Pasteur—but which seemed likely now to attain a development of the highest importance for the well-being of mankind. It was well, however, in the light of the past to remember that disease might be recovered from under many different forms of treatment. The practical certainties of our art in all ages had been sufficient for the welfare of mankind, and we must be careful never to subordinate to any vague ideas of what might possibly be curative of disease that which was, after all, the paramount object of our art—the relief of suffering.

Dr. Balfour then briefly welcomed the foreign guests, among whom were Gerhardt, of Berlin; Rosenstein, of Leyden; and Rosenbach, of Berlin.

Sir James Grant, of Ottawa, thanked Dr. Balfour in the name of the section, and said that in Canada bloodletting was sometimes necessary in sthenic cases in the country parts; the great point being to watch the peculiarities of individual cases, and treat them accordingly.

Cirrhosis of the Liver.—Dr. Alexander James then read a paper on the clinical varieties of hepatic cirrhosis, which he said were not so definite and well defined as was commonly supposed. The exciting causes were alcohol, exposure, and syphilis, hereditary or acquired; all these cases were not necessarily fatal, for with care and appropriate remedies some patients recovered and lived for years afterward.

Dr. Rosenstein had met with ascites and hæmatemesis, but never with jaundice. He had rarely met with cases due to alcoholism.

Dr. Ewart found it difficult to connect cirrhosis with alcohol. He had, however, met with cases in which vinegar taken in large quantities was apparently the exciting cause, and he instanced the case of a patient who had indulged largely in acetic acid, had been tapped fifteen times, and was still living.

Another speaker, whose name was not announced, mentioned the case of a boy who died with hypertrophic cirrhosis of the liver after indulging in highly spiced food; he became jaundiced and died from septic poisoning. A lady, too, who lived principally on entrées and champagne, had a curiously enlarged liver with a great rise of temperature: an exploratory puncture was made, and eventually the woman died, but a post-mortem examination was not allowed. Another patient, who had pain and enlargement of the liver, had fed upon highly seasoned food, but had not partaken to any extent of alcohol.

Dr. Rosenbach thought cirrhosis of the liver was usually associated with disease of the heart, but the two affections were etiologically independent of each other. The same pathological cause underlies all cases of cirrhosis.

Another speaker said that he had examined a great many drunkards and had met only one case of cirrhosis in some four thousand of them. Alcohol at the most opened the door, but there existed a more direct cause,

and if we could discover this we could put a stop to cirrhosis not only in the liver, but in the lungs and thyroid as well.

Dr. James, in closing, said that the point he wished more particularly to emphasize was this, that in atrophic cirrhosis the liver cells disappeared and their place was taken by fibrous tissue.

Dr. Osler, of Baltimore, then read a paper by Dr. Adami, of Montreal, on the "Bacteriology of Progressive Portal Cirrhosis," and exhibited photographs of a bacillus which he had discovered not only in man but in cattle, of which he had killed and examined thirty. It was very characteristic; the bodies were still warm when he made the autopsies, and cultivations of the bacillus, which was a very short one, were successfully made. He thought the micro-organism caused more than one disease by setting up a septicæmic action in the system.

Dr. Rosenstein doubted the identity of the microbes found in cirrhotic liver in the human subject and in the hypertrophic liver of cattle dying from pleuro-pneumonia.

Dr. Rosenbach then read a paper on "Locomotor Ataxia," but he spoke so fast and withal so indistinctly that his remarks were evidently not understood.

(To be Continued.)

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ECHOES FROM THE EDINBURGH MEETING.

London, August 5, 1898.

Edinburgh has eclipsed her former record. She has absorbed the medical interest of the week and entertained the association with a zest and success that cannot be surpassed. The sole topic of medical conversation is the meeting, in some one or other of its numerous aspects. Your staff of reporters furnish you with full accounts of the most important proceedings. Of lighter matters here follow a few, but your readers will understand that, as no one person can be in many places at once, this letter is a compilation. The remarks are not even confined to your staff, but reported as said or heard by members present. The I or the we, therefore, in different paragraphs may represent different individuals.

Next year's meeting is fixed to be at Portsmouth, and Dr. Ward Cousins is the president-elect. He has well earned the honor by his long devotion to the association, and his geniality and humor promise well for his presidency.

The new university buildings are entirely occupied by the Medical School. They were ten years building —1878 to 1888—and cost nearly £250,000.

The McEwan Hall is a truly magnificent structure, of semicircular form, the gift of a wealthy brewer, and cost over £120,000. It contains a magnificent electric organ, and the pillars, galleries, gilding, and mural painting are very imposing.

The new Royal Infirmary was begun in 1870 and opened in 1879. It is a noble pile, and an additional pavilion is now being built as a commemoration of the Queen's jubilee.

The acoustic properties of the McEwan Hall are not good. At any rate, where I sat I could hear very little of Sir T. G. Stewart's address, and was glad your reporter was more favorably located. Of the other addresses similar complaints were made.

The sections began on Wednesday, and a hard morning's work in the hot weather gave a desire for fresh air; so in the afternoon we—some thousand or so of us—drove out to Craig House, the beautifully situated, designed, and decorated asylum for the insane of the middle classes, where we were received by Dr. and Mrs. Clouston and Sir Alexander Christison. The grand hall, the public rooms, and two of the wards were open to visitors, and the lovely scenery excited much comment. Refreshment was provided in a large marquee, to the strains of an excellent band.

In the evening the McEwan Hall and the university quadrangle were thronged with people. Organ and stringed bands, Japanese lanterns, and refreshments seemed everywhere present.

There was an interesting reception at the site of the city hospital for infectious diseases now being erected. We were received by Public Health Committee Convener Baillie Pollard, a copy of whose work on "The Care of Public Health and the New Edinburgh Fever Hospital" was presented to each. The baillie told us that at first the corporations were not very willing to undertake the care of infectious cases, but having once undertaken it they were resolved to do it thoroughly.

I got to Edinburgh early and found the weather splendid. The finest city in the world looks its best in sunshine with a light haze softening the shadows and mellowing the distance. Plenty of others arrived at the same time. I was quickly booked for as much private hospitality as could be crammed into the time, and hope to survive the dissipation.

The tickets for the annual dinner were all sold before I applied, and I was glad of it. So, too, for the lord provost's ball—I don't dance and want a little rest in this whirl of excitements. But a friend tells me the dinner went off well, only there was too much speechifying and it was not over until midnight. About four hundred and fifty were present.

The principal and senatus academicus gave us a reception on Thursday afternoon in the university library. This is a long room with arched roof and bookcases at right angles between the windows, forming bays. The library has just been redecorated at the expense of Sir W. Priestley, M.D., who is M.P. for the university. He was present, and so were many of his London confrères. In fact, we seemed quite at home —so many faces were familiar. What with electric lamps and greenhouse plants, the library was quite brilliant.

Then we went to the reception of the College of Surgeons, where Sir John Struthers, looking still weak from a recent attack of influenza, received us most gracefully. The ladies, of whom many were present, circulated among the specimens in the museum and indulged their curiosity.

Thence to yet another reception, viz , to the College of Physicians, where marquees in the gardens across the road in front had been prepared and a garden party intended; but rain made most of us stick to the hospitable walls of the college hall—a handsome if not very large hall. Here, too, were refreshments, as there were at the sister college—indeed, everywhere and all the while.

A fellow with a statistical craze calculated that 739,513 cups of tea and coffee and 453,219 ices were consumed at the various functions held in connection with the meeting this week.

In the evening the ladies' committee entertained those gentlemen who did not go to the dinner and others at the Royal College of Physicians, with music, talk, and more refreshments. There was a brilliant and crowded assembly, where Lady Grainger Stewart won golden opinions. A concert was also given by the ladies in Queen Street Hall.

On Friday the sections sat until 1:30, but a quarter of an hour before this a golf party had started off to a match—for the weather was again delightful, the

rain of the previous day having only cleared and cooled the air.

A very large party went to Hopetown, where they were received by the earl and countess. Charming views, lovely weather, handsome trees, excellent music, and a warm welcome made this garden party successful among successes. Then the drive there beside the water, with views of Ben Ledi, Ben Vorlich, and Ben Lomond standing out in the clear air, was a delightful experience.

Another party went to Glasgow. Another was entertained by Dr. Ewart, professor of natural history in the university, at his residence, where visitors were shown the results of his experiments in cross-breeding. The horse-zebra hybrids in the professor's extensive stud were examined with the greatest interest.

On Saturday the graduation ceremony and honorary degrees represented the more serious part of the week end, and the excursions the more popular. Many of the visitors had previously left.

New Instruments.

A NEW SPUTUM BOX.

By STUART HART, M.D.,

NEW YORK.

The inconvenience met in the use of the ordinary glass bottle and the glass receptacle of the board of health for obtaining specimens of sputum for examination, and the difficulty in destroying these, have led

me to devise a receptacle which, I believe, will be found to obviate many of the objections to the older vessels.

The receptacle in question consists of a wooden box, three inches in diameter by one and one-half inches in height; the top is firmly held by a spiral screw turned in the wood. The interior of the box is made concave and painted black, to facilitate the selection of portions for examination and to prevent absorption of the contents. The advantages of the vessel may be summarized as follows:

1. The wide opening (permitting the specimen to be collected without smearing it on the outside of the box).

2. The lightness, inability to break, absence of absorption, and the security of the cover (permitting a specimen to be transported to any distance).

3. Internal form and color (allowing facility in selecting a portion of the specimen for examination without turning the whole from the receptacle).

4. The ease of absolute destruction by fire.

5. Cheapness and simplicity.

The method, pursued in so many laboratories, of spreading out a specimen of sputum (to be examined bacteriologically) on a glass plate which has been previously used for another specimen and presumably sterilized, cannot be too highly condemned. Sterilization may be made perfect, but the equally important cleansing cannot be satisfactorily accomplished, and misleading contaminations are the result of this faulty laboratory method. The specimen box here offered obviates the necessity of the use of the glass plate, avoiding thus one step associated with a possible error.

The accompanying cut has been furnished me by Messrs. Lincoln & Luchesi, of this city, who have taken great pains in constructing the receptacle according to my drawings.

77 West Fiftieth Street, July 8, 1898.

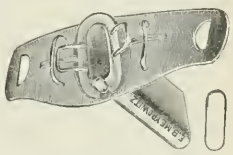
A NEW TRACHEOTOMY TUBE.

By GEORGE L. RICHARDS, M.D.,

FALL RIVER, MASS.,

OTOLOGIST AND LARYNGOLOGIST TO THE FALL RIVER AND EMERGENCY HOSPITALS.

The tracheotomy tube here illustrated was devised for a case of malignant laryngeal disease, in which the ordinary tube was worn with considerable discomfort and failed to furnish a sufficientamount of air. For adults who must for any cause wear a tube for any length of time, this tube has decided advantages. It furnishes an abundant supply of air, is not easily clogged, is worn without especial discomfort, and does not prevent speech or laryngeal breathing, as the finger placed over the end will completely close it. This latter is an advantage, as it allows the person to use what power of phonation may be left. For cases such as the one for which it was devised, in which the swallowing is difficult and more or less food and liquid get into the trachea, the food and liquid can be coughed out through this tube with the minimum amount of effort, far less than when the curved round tube is used. This tube should be just long enough to pass into the trachea about one-eighth to one-fourth inch. The one here illustrated was made by a jeweller from a hard-rubber model, but any instrument maker could make one from the cut and probably improve on the original. The lower side should be a little longer than the upper, to compensate for the backward direction of the trachea. The tube itself should be straight, attached to the shield in such a way as to give it a slightly downward direction from before backward. There is an inner tubes as in the usual tracheotomy tube.



Gall-Stone Solvents.—We have no evidence that gall stones are ever dissolved by substances taken internally for that purpose by patients. Olive oil is very frequently administered. There are several reasons why it does not act therapeutically as a solvent. 1. Oil cannot be expected to travel up the gall ducts from the duodenum, because the peristaltic action of the ducts is toward the duodenum from the liver, and this peristaltic action is presumed to be unceasing. 2. If oil could travel against the peristaltic effort of the gall ducts and enter an open gall bladder—many are not open—it would be at once mixed with bile. 3. Undiluted sweet oil, in which I kept gall stones for weeks at various temperatures, produced no appreciable effect beside a softening of the external layers of some stones. So unimportant was its action that it was not thought worth while to include it in the further tests. What sweet oil does do is to carry toxins out of the alimentary tract pretty rapidly, and it relieves the patient of the element of intoxication from that source.—Robert T. Morris, "Lectures on Appendicitis and Notes on other Subjects," p. 90.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 13, 1898:

	Cases.	Deaths.
Tuberculosis	148	120
Typhoid fever	34	13
Scarlet fever	58	3
Measles	70	4
Diphtheria	101	15
Laryngeal diphtheria (croup)	5	7
Chicken-pox	15	0

A "Home-Made" Milk Sterilizer.—Dr. McClanahan states that a cheap and efficient sterilizer can be made in the following manner: Take an ordinary one-gallon tin bucket, twelve inches high, having a movable, closely fitting lid. Have a handle soldered to one side for convenience in handling. Have a false, perforated bottom, to which are attached three legs, each one inch long. This is to be slightly smaller in circumference than the bucket, so that it will go inside and rest upon the bottom of the bucket. In the lid a small opening is to be made for the escape of steam. This sterilizer can be made by any tinsmith at a nominal cost.—*American Journal of Obstetrics and Diseases of Women and Children.*

Longevity of Physicians.—A French statistician has discovered that in the sixteenth century the average duration of a doctor's life was only thirty-six and one-half years. In the seventeenth century it reached forty-five and two-thirds years, in the eighteenth century forty-nine and two-thirds years, and at the present time he finds it is fifty-six years. The same inquirer purposes to ascertain whether the average longevity of patients has increased in the same proportion.—*Toledo Medical and Surgical Reporter.*

The Biograph in Medicine.—Dr. Fincham, writing to the *Amateur Photographer*, London, points out that the cinematograph as regards medicine and surgery is rich in potentialities. "Just as the discovery of the Roentgen rays first appealed to the wonder-loving public as a scientific curiosity and now is deemed an essential part of the armamentarium of every hospital, so in the future will the cinematograph be regarded as a necessity for the pictorial record of suitable cases."

The Total Number of Blind in the United States is nearly 49,000, or 976 in each million of the population. The number of blind reported as receiving instruction is 4,691. The number of blind who are also deaf-mutes is: whites, 84 males and 107 females; colored, 28 males and 29 females. Blind and idiotic: whites, 595 males and 463 females; colored, 66 males and 62 females.

Tea.—The United Kingdom consumes 600,000 pounds, or about 4,000,000 gallons, of tea every day, which is as much as is used by the rest of Europe, North and South America, Africa, and Australia combined.

Netley Hospital.—It is claimed for Netley Hospital that it is the longest building in England, being nearly a quarter of a mile long.

Realizing on the Effects.—An amusing tale is told by a country doctor in England. He had been attending for a considerable period a parson, and, according to custom, now fortunately becoming antiquated there, attending him gratis. When in due course the parson died, his widow wrote to inquire how much the doctor would allow her for the medicine bottles.

Australia has No Orphan Asylums.—Every child who is not supported by parents becomes a ward of the State, and is paid a pension for support and placed in a private family, where board and clothes are provided.

Acetylene is the newest cure for cancer. Carbide of calcium is applied to the cancerous surface and then moistened with water. Acetylene is at once evolved, producing at first a burning sensation and then exercising its curative effect.

The Bicycle.—Prof. H. C. Wood declares that "the bicycle is the great calisthenic of the world."

A Simple Tonic.—An English weekly journal is responsible for the following anecdote: A Birmingham physician has had an amusing experience. The other day a somewhat distracted mother brought her daughter to see him. The girl was suffering from what is known among people as "general lowness." There was nothing much the matter with her, but she was pale and listless, and did not care about eating or doing anything. The doctor after due consultation prescribed for her a glass of claret three times a day with her meals. The mother was somewhat deaf but apparently heard all he said, and bore off her daughter, determined to carry out the prescription to the very letter. In ten days' time they were back again, and the girl looked quite a different creature. She was rosy-cheeked, smiling, and the picture of health. The doctor congratulated himself upon the keen insight he had displayed in his diagnosis of the case. "I am glad to see that your daughter is so much better," he said. "Yes," exclaimed the excited and grateful mother; "thanks to you, doctor! She has had just what you ordered. She has eaten carrots three times a day since we were here, and sometimes oftener—and once or twice uncooked—and now look at her!"

Health Reports.—The following statistics concerning small-pox, yellow fever, cholera, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending August 13, 1898:

SMALL-POX—UNITED STATES.

		Cases.	Deaths.
Alabama, Butler County	Jan. 1st to Aug. 6th	300	
Forest Home, Butler Co.	During June	..	1
Gordonville	August 6th	..	5
Haynesville	August 6th	..	2
Lowndes County	August 6th	25	2
Morganville	August 6th	..	1
Michigan, Seneca Township	Present, but number of cases not reported.		
New Mexico	Prevalent to a great extent, notably on line of Santa Fé R.R.		
Tennessee, Cleveland	During July	1-	
Memphis and suburbs	During July		

SMALL-POX—FOREIGN.

Belgium, Antwerp	July 16th to 23d	..	
Ghent	July 16th to 23d	..	1
Ghent	July 23d to 30th	..	1
Colombia, Valencia	July 25d	1,000	
India, Bombay	July 5th to 12th	..	1
Calcutta	June 25th to July 2d.	..	3
Madras	June 25th to July 1st	..	1
Madras	July 2d to 8th	..	1
Japan, Osaka and Hiogo	June 25th to July 2d.	1	
Osaka and Hiogo	July 2d to 8th	4	
Russia, Moscow	June 25th to July 2d.	6	
Moscow	July 2d to 8th	15	
Odessa	July 9th to 16th	4	
St. Petersburg	July 9th to 16th	2	
Sweden, Christiania	July 16th to 23d	2	
Uruguay, Montevideo	June 19th to 26th	1	

YELLOW FEVER.

Brazil, Rio Claro	April 26th		17
Rio de Janeiro	June 24th to July 1st	33	21
Taboticabal	April	106	42
Tahir	May	3	1
Colombia, Carthagena	July 8th to 15th	..	2
Mexico, Tampico	July 25th to 31st	..	9

CHOLERA.

India, Bombay	July 5th to 12th	..	3
Calcutta	June 25th to July 2d.	..	9
Japan, Osaka and Hiogo	July 2d to 9th	1	

PLAGUE.

India, Bombay	July 5th to 12th	..	53
Calcutta	June 25th to July 2d.	..	20

THE DELIRIUM OF INSANITY.[1]

BY HIRAM ELLIOTT, M.D.,

MANHATTAN STATE HOSPITAL, NEW YORK.

BEFORE proceeding to the specific discussion of the subject of this paper, I shall give a brief outline of the way the normal mind is thought to be developed. I do this because it will be maintained herein as a fundamental principle that the very same laws govern the action of the diseased brain as govern its action in health. It will be held that just as the sound mind is developed through certain physiological steps from the healthy brain, so is delirium a legitimate product of that organ in disease. And further, it will be contended that disordered cerebral action does not result in the creation of any new product, but rather in the modification or failure in the normal evolution of the old.

The brain is a reflex nerve centre endowed with consciousness. As a nerve centre the scheme of its action is a simple one. It receives sense impressions and gives out motor stimuli. So far it does not materially differ from the spinal centres, but as endowed with consciousness a new series of phenomena are made to appear. Sensory stimuli, instead of passing over directly to the motor side to reissue at once in action, come into view as it were. We are conscious of them. They are experienced, are compared, are elaborated, and are controlled.

Consciousness first busies itself with the sensations themselves. It notes how they affect the organism, whether they produce a sense of well-being or of discomfort, whether they please or depress. In this way it originates what are termed the feelings: and those feelings arising directly from sensations presented are termed presentative. These are registered and accumulate, and are called up by consciousness to be combined with those newly presented to form what are known as presentative-representative feelings, and with each other as representative and re-representative feelings. A series is thus formed passing from the simple to the complex, from the concrete to the abstract, and extending farther and farther from the original sensations, yet never becoming wholly independent of these sensations as registered in the brain.

Again consciousness takes note of the relations of the sensations received by the brain. It locates them, compares them with experience and with each other, combines these relations into groups more and more complex, and calls them up again and again in new and varying combinations. The cognitional series is thus formed, also passing farther and farther from the original impressions, but never becoming independent of their registration in memory. This is intelligence, originating like and with the feelings in sensation. Beginning with the simplest idea, it passes on to the more elaborate and complex, from the concrete to the abstract, from the first presentative cognition of the child, which fades even before the sensation from which it arose, to the sustained production of re-representative cognitions in the trained adult mind, evolved by consciousness from the vestiges of sensations whose originals had long before disappeared.

Thus between the simple taking in and giving out, as seen in the spinal centres, are developed these series of feelings and cognitions, all that constitutes the emotions and the intelligence, the ever-widening realm of mind. Here as in a sealed chamber sensation very imperfectly but indelibly pictures the environment, and consciousness, guided by its own light, moves silently and swiftly among the figures, noting, comparing, arranging, evolving therefrom the highest product of the human organism, the noblest thing in the universe.

And the extent and quality of this psychological product, then, will depend on three things: the accuracy and vividness of the sensory images, the richness and the availability of experience, and the activity of consciousness. As these vary so will the product vary. The sensory apparatus is a wonderful mechanism, but not more wonderful than imperfect. Even under the most favorable circumstances of endowment and education it is always defective. It is never alike in two individuals, nor are its parts equally well developed in the same individual. In one person, for instance, sound images are produced with great clearness, while form pictures are blurred and indistinct; in another, sensation vividly portrays tactile stimuli, but will not respond readily to color; in a third, no good sensory images are produced at all. Indeed, of the multitudinous impressions sent into the most highly educated and sensitive brain, only a very narrow minority come so fully into view as to give rise to feelings and cognitions, or are registered with sufficient definiteness to be of any service to memory. To put it epigrammatically, the best sensory images are poor, and the vast majority are so bad that consciousness pays little heed to them, at least as far as ideation is concerned; and they leave behind no available traces whatever. Almost the entire series of subjective sensations is of this nature.

Experience is also a variable quantity. Age, opportunity, and natural capacity are factors controlling its richness. It is a standard by which new perceptions and conceptions are judged and to which they may be added. In a few people it is very wide in extent and vivid in character. When wanted for purposes of comparison, its elements are readily available. A direct continuity between the presenting image and the vestiges of numerous former ones is readily established. In most persons, however, experience is very narrow and confused. Both the emotional and the cognitional series are defective and fragmentary. Hence re-presentation is not only difficult, but also the images called up are blurred and incomplete. And as memory is defective, so are additions thereto correspondingly few and imperfect.

Again, the activity of consciousness or attention, while it depends chiefly on cerebral energy, will be affected materially by the character of the sensations received and by the availability of those already registered for purposes of comparison. Attention is like all servants, in that it works best along the easiest lines. When the sensory and ideal images are distinct, little effort will be required for the evolution

[1] Read before the Brooklyn Society for Neurology.

therefrom of feelings and cognitions. Cerebral energy will be in excess and give rise to a sense of satisfaction and freedom and power. On the other hand, when these images are lacking in definiteness or number, attention soon wearies and flags, cerebral force is quickly expended, and we experience a feeling of restriction and insufficiency. Our individual proclivities are developed in this way. We follow certain lines of thought or action, mainly because they are most attractive to us and offer the least resistance. In the lower types of man, indeed, the inclinations are supreme, and in the evolution of mind in them consciousness knows no higher direction.

But as we ascend the scale of mental capacity we find the product begins to direct the factor, the psychical to control the physical. Masses of cognitions form, which seem able, as it were, to monopolize cerebral activity, to preoccupy consciousness. Very many sensory impressions are received which result in neither emotion nor idea. There is acquired the power of ignoring what is extraneous, and of confining the action of consciousness to the appropriate series of sensations, or their vestiges, which are esential to serial thought. In some individuals this power is very great. Even out of the faded tracings of former sensory images they are able to construct new and more vivid series of ideal pictures, which are themselves also capable of sustaining thought or of actual reproduction, as, for example, in historical paintings. It must be remembered, however, that these representations are not sensory images and never can become such. Moreover, the trained mind is not only able to pursue this abstraction, but is also able to put the whole series to flight or to turn the trend of thought into an entirely different channel. This is concentration.

Now the end of all thought is to direct the action and promote the welfare of the body. Nature is constantly calling for gratification. The physical necessities and the acquired tastes make no uncertain demands. Sensations are received in the brain, out of which corresponding cognitions and feelings arise and accumulate, and the masses thus formed, in their striving to discharge themselves as motor stimuli, constitute what are termed the desires. If opposing masses of cognitions form, each adds to itself by a process of selection, until one mass overbalances the other, and, drawing after it sufficient cerebral force, is translated into motion. This necessary issue of the thought in action is termed will, and the process by which one mass of cognitions rises superior to all others and determines cerebral action in a certain direction is called decision. To recapitulate in one sentence: Out of the sensations received by the brain consciousness evolves the emotions and the intelligence; these, being concentred upon the attainment of a certain object constitute a desire; and this in turn, when of sufficient intensity to force its discharge through the motor centres, results in what is termed a volition.

While the foregoing refers more directly to objective sensations, it also applies to the vague sensations arising within the body and which are termed subjective. While these scarcely come specifically into view at all, they play a very important part in the production of the feelings. In all diseased conditions the feeling of illness and wretchedness is produced in this way. The product is painfully manifest, though its factors may only be guessed at or are wholly undiscoverable. Ordinarily in health the feelings are in a condition of partial abeyance, ideation and volition occupying almost the entire foreground. We move along at a certain level, scarcely conscious of our existence unless we are forced above or below that level. Normally we may be said to be in a condition of intellectual activity and emotional indifference.

The term insane delirium may be defined as prolonged deviation of the intelligence from the normal, due to brain defect or disease, the chief phenomena manifested being incoherence, irrelevance, illusions, hallucinations, and delusions. I have said that these conditions are due to disease or defect in the brain, but as that organ presides over all nutrition, prolonged disease therein usually results in permanent change in the nerve trunks or at their peripheral expansions as well. Sometimes the disorder along the courses of the nerves or at their terminations precedes or exceeds disease in the cerebrum, as, for example, pressure upon the auditory nerves from meningeal congestion or inflammation, or irritation of the pneumogastrics by the gravid uterus. In this way may originate sensations which are so startling and so powerful that consciousness is active only in their direction. The other centres, receiving little or no attention, become sluggish or inoperative, and thus is disordered cerebral action induced. In very susceptible persons, indeed, the irritations referred to may be the immediate substratum of false feelings and cognitions.

Pathological changes in the central nervous system, whether congenital, nutritional, degenerative, or inflammatory, manifest themselves first in disordered sensations. Sensory images, imperfect even in health, become more imperfect. They may be so vivid that they are painful and distracting, they may be blurred and indistinct or otherwise defective, or the receptive apparatus may be so insensitive that it does not seem to respond to any stimulus and presents no sense pictures to consciousness at all.

Again, the seriality of the sensory images may be disturbed. In exalted and hyperactive states these imperfect images may present themselves so rapidly and come from so many sources that they all run together, and any cognitions evolved therefrom are correspondingly confused and fragmentary, and devoid of any proper relation to each other. In depressed conditions, on the other hand, they may be so slowly formed and so few in number that the connection between them is lost and serial thought becomes impossible. Sometimes, indeed, the whole cerebral energy seems concentrated upon a single stimulus, as in ecstasy or rapture. This lack of proper sequence in sensory images is a frequent cause of incoherence.

A third element in the causation of delirium is a decrease in the availability of experience as a standard of comparison. Even in weariness or anger the store of our knowledge frequently fails us, and in fright may desert us altogether. In brain disease this reduction is one of the first things to happen. Here, possibly as the result of dislocation or destruction or weakening of the protoplasmic processes or axis cylinders of the neurons, consciousness seems no longer able to force its way readily along its accustomed paths. This is especially true of those paths recently formed. It makes short cuts, so to speak, or excursions into wrong areas, or possibly is brought to a standstill. The representative factor in ideation is consequently at fault. Hence the ideas developed may not have the proper relation to the sensation initiating them; they may be irrelevant. Or, on the other hand, they have not the proper relation or consecutiveness to each other, and we have incoherence. Again, experience may not be available at all, as in conditions of amnesia, and if consciousness be correspondingly inactive, the faint and fragmentary images fade without an evolution of emotion or idea, as in profound dementia and stupor.

The chief points, then, of the ideational apparatus where anomalies arise are, first, in the sensory nerves and their peripheral and central expansions. Stimuli may be abnormally originated, or they may be improperly transmitted to or received in the sensory centres.

Second, in consciousness, which may be too active, preoccupied, or in abeyance. Third, in the quality and quantity of experience available as a standard of comparison. For example, even in health we do not see all that stimulates the retina, we do not see all the images that are transmitted to the visual centres, we do not see all those that rouse consciousness into activity, we do not correctly see even the infinitesimal few that we think we have carefully compared with the corresponding elements of our imperfect experience. If in health we are the sport of our environment, how shall we fare in disease?

Failure to receive and interpret sensory stimuli correctly results in illusion. These stimuli are usually normal and applied at the periphery, but they may be false and applied anywhere along the nerve trunks right up to their central expansions. And the fact must not be lost sight of that they are always afferent. The sensory centres are never and can never be stimulated to the production of true sensory images excepting from without, and their psychical stimulation to this effect is impossible.

Illusions are presentative-representative errors, and falsity may exist in one or both of these elements. Sensory images may be false and still further misconstrued, or, being true themselves, they may be misinterpreted in terms of predominating thoughts or emotions. It is as though obtrusive ideal images came in front of the sensory ones, there to shut off the full view of experience and to give rise to the belief that they themselves are the real presentations. In this way the ticking of the clock is sometimes interpreted by the melancholiac as a torrent of abuse. The patient, wretched and unhappy, is upbraiding himself for sins he thinks he has committed and for which he believes he is being punished. By and by his thoughts and the clock strike step, as it were, and consciousness, confused and preoccupied, clothes the indistinct auditory images with the most obtrusive and only available item of experience at the time—the patient's own self-recriminations.

Sometimes a trifling stimulation of one of the senses results in a most elaborate illusion involving other special senses as well. Here the representative element is much in excess of the presentative. For example, an epileptic patient told me that at times, when a certain other patient approached her, something in the latter's walk called up a complete image of her father. The looks, gestures, voice, and very words were his, and the room was transformed temporarily into the patients' home. When the false picture faded, she heaped the wildest abuse upon her fellow-patient for the deception. Here, upon a few meagre outlines was developed a complete scene, in which all the details and coloring were supplied from the patient's experience and emotions, and in which consciousness failed to distinguish sensation from memory or experience, and referred the whole to sensation. And the rapidity with which these illusions sometimes form and are acted upon is very great. In postepileptic fury the patient, still partly unconscious and in a condition of wretchedness and terror, sees his attendant; fear and a person mean an enemy, an enemy means danger, and self-defence, and assault, and possibly murder.

Sensory image defective, attention weak or preoccupied, memory incorrectly or ineffectually stimulated, cognition false—such is the usual skeleton of an illusion. Illusions, then, are false presentative-representative cognitions arising out of misconstruction of sensory stimuli. And if these rest on a pathological basis and are allowed a dominating place in the mind, they constitute an element of insanity.

Every insane person has illusions. In many cases the delirium manifested consists of little else. Examination of forty selected cases, whose only qualification consisted of the ability and willingness to describe their symptoms, showed the presence of illusions in every instance, and in the majority of patients revealed disorder of sensation corresponding thereto. In some chronic cases all the special senses were so affected, and the psychical contact with the physical was always through a false medium. One patient declared that everything was changed. People's voices sounded different, when she looked in the glass her face seemed that of a dead person, her food smelled and tasted poisonous, her needle did not feel right in her fingers, and her limbs moved as though loaded with lead. In some cases illusion of one sense only was elicited, and occasionally it was more marked on one side than on the other.

As to relative frequency, illusions of sight and hearing stand first. This arises out of the fact that these are the two chief channels of sensation. They are especially common in acute insanities, probably because the power of fixing the attention is so greatly compromised. I have had a maniacal patient recognize me as ten different people in as many minutes. Upon the sensory image of my face consciousness seemed to project memory pictures at random, and then to accept them as real.

Alcoholic patients are very prone to this form of error. Here, from nutritional or circulatory changes in the retina, it becomes studded with minute areas and fine lines that are more or less insensitive to light. These appear to the field of vision as corresponding moving shadows, and the wretched patient interprets them as rats and snakes. Insane persons who are partially blind may have illusions for obvious reasons; those who are totally so from irritations along the optic tracts.

A noteworthy phenomenon sometimes seen with auditory illusions in recent cases is a change in the patient's voice. It becomes like that of a person partially deaf, and is lacking in timbre and altered in pitch. This arises out of disorder of the sense of hearing, indirectly through which the tones of the voice are registered. Any sound may originate an illusion. The patient's own words may be echoed back to him altered in tone and meaning. Irritation in the auditory apparatus may give rise to them even in persons with acquired deafness.

Illusions of taste and smell are probably next in frequency, and depend chiefly upon alterations of the mucous membrane and secretions of the mouth, throat, and nose. As is very well known, very slight changes in the health cause corresponding changes in the tongue, which not only originate foul tastes therein, but also compromise its ability to transmit the normal sensations of sapidity. Illusions here usually refer to poisoning or befoulment of food, and they have a special clinical importance as frequently explaining why many patients refuse to eat, besides affording a valuable therapeutic hint. In a similar way foul breath may originate illusions of smell, or they may depend directly upon disorder of the nasal mucous membranes. The idea that illusions of smell point to disease of the frontal lobes I have not been able to confirm.

Visceral, tactile, and muscular illusions also form an important part of the delirium of insanity. All false ideas regarding electricity, inhabitation by animals, pregnancy, violation, vermin upon the skin, changes in stature, and the like, are of this nature. Here the presentative element is usually more at fault than the representative. One patient, who believed that if his skin was wet it could never be dried, and who possessed such marked sensitiveness to heat that he slept without coverings throughout the coldest winters, was found to have a remarkably altered condition of the skin. There was an almost total loss of hair on

his body and limbs, and where the hairs were gone the follicles were atrophied and consisted of minute depressions with a pale shining base. The nails of his fingers did not separate normally from the matrix, but carried it out to their ends. Tactile sensibility was much weakened, but that to heat exaggerated. He could not readily distinguish foods by taste or smell, and all nourishment caused the most intense disgust. Sight and hearing seemed abnormally acute, but after repeated critical examinations of his face in the mirror he pointed out many ways in which its contour was changed. In this case every item of delirium manifested was directly traceable to changes in the sensory apparatus. Although he had been a man of the solidest judgment and was quite aware of the changes referred to, yet the environment was in many ways so distorted to him, and the false images were so distinct, that illusions founded thereon were ruling principles in his life.

Hallucinations are representative errors. They are entirely of psychic origin, and are constructed out of vestiges of former sensations. Every concrete thought is accompanied by a faint ideal image, and if attention is directed intently thereto this image is made to stand out in bold contrast to the other contents of memory. Now the recentness of a sensation is determined by the vividness of the corresponding registered vestige. The more vivid is this, the more recent is the sensation assumed to be. In health the mind constantly proves this assumption by contemporary events or otherwise. But in mental disorder not only is this power of comparison weakened or lost, but also the ideal images, by continued and intent contemplation of them, are rendered abnormally distinct. They seem just to have been registered, and the mind accepts them as sensory. For this reason, the melancholy mother who spends days and nights poring over the mental picture of her dead child, when roused from her reverie, maintains that she has actually seen that child. She does so, not from any sensation she has experienced, but because in her abstraction and confusion she is not able to give this confronting vestige its proper place in her experience.

Hallucinations, then, are psychical images believed to be sensory. The images themselves may be integral representations, and the error consists entirely in the belief regarding their origin, as in the case just cited. Usually, however, they involve additional falsity in their construction, and, indeed, they may be entirely fictitious and underlie concepts that are wholly false.

Hallucination is notably exemplified in those patients who claim that they hear their own thoughts. One patient constantly heard herself cursing the priest, and when she afterward became excited she did curse him roundly. Word images corresponding to her profane thoughts were formed in the auditory centres, and referred in the usual way to that of speech for expression. Here their utterance was inhibited for a time because of their character, and the mind mistook the original vivid images for the anticipated audible words. When the inhibitory power was further weakened, her thoughts forced their translation into sounds which supplanted the hallucinations. The phenomenon of talking to self, so common in patients with weakened self-control, is accounted for in this way.

Three factors at least enter into the production of an hallucination—weakening of object consciousness, intensification of subject consciousness, and reduction of the comparing power. Especially in melancholia are these factors marked, and hallucinations correspondingly common. Fears and suspicions originate with the painful emotional state, and the confused sufferer, no longer able to distinguish clearly what he dreads from what actually happens, refers all to sensation. Often the contemplation of a delirious concept is so intense that the patient is oblivious to all else. Fragments of former sensory images are selected from experience, and united, sometimes in the most incongruous way, until an elaborate vision is constructed. This becomes comparatively more and more distinct, until its vividness exceeds that of sensation. The mind has no choice but to accept it as sensory.

Hallucinations differ intrinsically from illusions. They are fictions, while the latter are only distortions. Illusions are false mental images arising out of sensations; hallucinations are mental images falsely referred to sensation. Illusions that are at all fixed usually depend on change in the nervous mechanism, and may be unilateral; hallucinations have no physical relations at all. Inattention alone often accounts for an illusion, but the belief that the special senses are operating, when they are not stimulated at all, implies a serious involvement of consciousness and judgment. Illusions are exceedingly common; hallucinations are rare, and much less definite in character and outline.

As to relative frequency, hallucinations stand in about the same order as illusions, and for the same reasons. Those of hearing and sight come first and in the order named. Auditory and visual images are much more definite than those of taste, smell, and touch, and are therefore more easily called up. In fact, sounds and forms are not only necessary for the easy expression of thought, but vestiges of them form the chief part of the groundwork of the mind, and normal mental development and activity are hardly possible without them.

As to contents, illusions and hallucinations are very similar. In fact, they are frequently found together, the one shading into the other so gradually that it is often very difficult clinically to tell where illusion ends and hallucination begins. They both partake of the same general coloring as the other elements of insanity present. The depressed and alcoholic patient interprets his retinal disturbance as snakes and rats. The quiet, cheerful, organic dement sees kittens playing on the carpet from the same cause. The illusions usually bear a close relation to the patient's thoughts and habits previous to his alienation, as when the insane criminal sees officers of the law pursuing him or hears his crimes rehearsed in his ears. Sometimes they are complementary to prevailing thoughts or emotions, as when the starving traveller sees visions of the food of which he has so long been deprived. No other phenomena of insanity have anything like the interest or importance as these. Especially is this true of illusions which are the most concrete symptoms of mental alienation, and which more than any others show the intimate connection between mental disorder and brain disease.

Delusions are re-representative errors. They are neither misinterpretations of sensation nor false ideal images referable thereto, and, while they frequently have their origin in illusion or hallucination, they may arise independently of either. They are faulty products of reason, defective abstractions, false beliefs regarding the personality as a whole.

Beliefs are ultimate conclusions, and their soundness will depend upon the character of the more concrete elements from which they are derived and upon the method of their deduction. They are never perfect even in health, for even under the most favorable conditions and after the most careful deliberation, perhaps all our beliefs contain error and many are absolutely wrong. But this error is not delusion. Even insane persons hold many erroneous beliefs which cannot in any sense be regarded as delusions. The dement may assert that Christmas comes in summer,

but that is only a bad guess. His memory is at fault.

The essential condition in insanity is the falsification of the ego. Changes in the sensory apparatus, in consciousness, and in memory, and their results as already described, contribute to the formation of a new personality. Now it is only those abstractions into which the concept of this false ego strongly enters that may constitute delusions. Beliefs on other topics may be perfectly sound, and if false they come into the category of mistakes. In many patients all thought is made to centre around and include this false concept, and if the mind attempts to correct the resulting error, the intruding element continues to present itself and falsifies the correction. A morbid egotism shows itself everywhere. The patient becomes a laughing-stock to himself; he is deluded.

A delusion, then, is a false belief of an insane person arising out of and referring to changes in his personality, due to brain disorder. As the ego is depressed or exalted, so are the corresponding delusions restrictive or expansive, and as the personality is reduced to that state of indifference to which all insanity tends they gradually lose character and fade away.

It is a physiological principle that when any organ functions abnormally it gives rise to a sense of discomfort. This is especially true of the brain, and it may be stated, practically without qualification, that the fundamental false belief of an insane person is restrictive. In fact, depression characterizes the onset of all forms of mental alienation, sometimes amounting at once to almost total obscuration of the intelligence, as in acute stupor.

Ordinarily, however, the process of mental alienation is a gradual one. Attention becomes more and more introspective, an increasing sense of resistance is felt in thought and action, and discord arises between the individual and his environment. The bodily functions fail. A morbid ego is thus developed, whose essential quality is that of unworthiness. In a certain proportion of cases this goes on until the old personality is entirely subjugated, and the sufferer, overcome with a sense of his insufficiency, may believe that he is utterly ruined and lost. Cerebral energy is almost wholly transformed into mental pain, and any excess may issue as restlessness or burst through all restraint in the form of agitation. Illusions and hallucinations are frequent; delusions rarer and not essential. This is the type of restrictive delirium.

But many persons are incapable of prolonged depression. Beyond a certain point, the very influences that depressed become excitants. Inhibitory power in them is soon exhausted, and especially is the cerebral circulation readily released from its control. In such the preliminary depression referred to soon gives way to exaltation. The abnormally increased cerebral nutrition gives rise to an excess of cerebral energy, which is readily transformed into extravagant thought and action, and the patient believes he has risen superior to his former self and to his fellows.

In some cases, indeed, inhibitory power is soon lost and the functions of brain and body run riot, nervous energy is rapidly exhausted, the temperature rises, nutrition fails, and emaciation ensues. Sensation is perverted, illusions and frequently hallucinations occur, and fragmentary delirious concepts follow each other in the wildest confusion. Appreciation and consciousness are soon lost, and any flaring up of the dying vital energy relieves itself in purposeless action and meaningless muttering or shouting. The patient sinks into a typhoid condition, and death usually closes the scene. Such is the type of the delirium of exaltation.

Most cases of mental alienation, however, do not approach either of these extremes. The personality is transformed without violence. There is no sudden arrest of cerebral activity or consequent accumulation of nervous energy to be transformed into mental pain or to burst forcibly through inhibitory control. Immediate relief is afforded in perverted ideation, and that degree of mental calm necessary for the operation of reason, at least in an imperfect way, is preserved. Illusions and hallucinations occur, but it is here alone that the conditions are favorable for the development of the clearly defined delusion.

Here, because of the greater stability of the underlying pathological conditions, delusions are less fleeting than in the acuter types, and tend to persist without change. Entering the mind insidiously, they develop along with it and become an intrinsic part of the mental fabric. When once the concept of the ego has become distinctly false, it modifies all thought to some extent, so that not only intrinsic conditions, but also the behavior of the environment begins to be interpreted more and more according to a false standard. This may go on until the identity is lost and the patient believes he has been transformed into a different being. Those cited cases in which a single delirious concept seems to have persisted without diffusion for years in an otherwise normal mind probably are to be accounted for by defective observation.

The tendency of delusions to arrange themselves around some central false idea is known as systematization. The more fixed they are, the greater this tendency becomes. The significance of the systematized delusion depends on the fact that, with the reason still active and in a time of mental calm, the mind deliberately adopts it as an intrinsic and active element of itself.

As to contents, delusions usually coincide with the patient's prevailing emotions, and as a rule bear a pretty constant relation to his temperament in health. They may refer directly to his own person, or relate to the conflict which of necessity soon arises between the alienated and his environment. Expansive and restrictive delusions are very frequently found together, and especially is there a tendency for grandiose ideas to arise as complementary to those of persecution. It is for the relief afforded thereby that the patient who is harassed by all sorts of persecutions maintains that he is superior to his enemies, and that these annoyances are directed toward him because of his excellence. Thus we may have falsity along the entire length of the cognitional series: false sensations, illusions, hallucinations, delusions.

The insane impulse and many other interesting topics must be reserved for a subsequent paper.

Primary Lupus of the Larynx.—In a paper read before the American Laryngological Association Dr. Emil Mayer, of New York, concluded as follows: 1. A primary lupus of the larynx does not exist. 2. The secondary lupus of the larynx is a painless affection and may escape detection for many years. 3. Tubercle bacilli are present in but a few cases, and even then are difficult to find. 4. In appearance laryngeal lupus resembles syphilis more than it does tuberculosis of the larynx. 5. The absence of adhesive bands, which are always present in the later stages of syphilis, is characteristic of lupus. 6. The prognosis of laryngeal lupus is *quoad vitam* good, *quoad sanationem* doubtful, but the patients are always in danger of pulmonary or miliary tuberculosis. 7. The treatment consists in local applications of lactic acid, nitrate of silver, chloride of zinc, iodine, menthol, or galvanocautery. Internally, creosote, cod-liver oil, and iodine preparations are advisable. In obstinate cases surgical measures (laryngotomy and extirpation of the diseased areas) must be considered.

THE TREATMENT OF INOPERABLE SARCOMA WITH THE MIXED TOXINS OF ERYSIPELAS AND BACILLUS PRODIGIOSUS: IMMEDIATE AND FINAL RESULTS IN ONE HUNDRED AND FORTY CASES.[1]

By WILLIAM B. COLEY, M.D.,

NEW YORK,

ATTENDING SURGEON TO THE NEW YORK CANCER HOSPITAL; ASSISTANT SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

The question of the value of these toxins in the treatment of inoperable sarcoma is one that depends for its solution, not upon high authority or *a priori* arguments, but rather upon facts derived from careful observation and large clinical experiences. No one could possibly witness a number of hopelessly far advanced inoperable sarcomata, the diagnosis of which had been confirmed by the most skilled pathologists, entirely disappear under injections of these toxins, without being convinced that there is something of value in them. The successful cases, a number of which have now remained well beyond three years, more than offset the many failures.

I have decided in the present paper to confine my remarks almost entirely to sarcoma, in order to correct, if possible, the misunderstanding so common among men who have read the subject but casually, that the toxins are advised indiscriminately in all cases of inoperable cancer, whether sarcoma or carcinoma. The successes in carcinoma have thus far been so few in number, and these mostly but temporary, that I think it wise to restrict the toxins to sarcoma and, it is needless to repeat, to inoperable sarcoma. I have never advised the treatment in cases of sarcoma that were amenable to operation, unless it be in a few cases in which a brief period of treatment was advised with the idea of avoiding amputation of a limb. If a tumor be in the soft parts, and especially if spindle-celled, I think it justifiable, and even strongly to be advised to make an attempt to save the limb. I have now a patient well nearly two and one-half years with rapidly recurrent spindle-celled sarcoma of the right hand, in which amputation of the arm would have been done had not the growth disappeared under the injections. This case cannot as yet be considered as one of cure. Drs. L. L. McArthur and John E. Owens, of Chicago, have had two cases—the one a spindle-celled sarcoma of the calf of the leg, and the other a myeloid sarcoma of the tibia—in both of which the tumor disappeared under the toxins and made amputation unnecessary. These patients are both well after more than three years. Dr. McArthur has had a third case of rapidly recurrent sarcoma of the arm, in which amputation was advised and refused. The tumor disappeared under the treatment and the patient has remained well. I do not believe the chances of a cure by amputation are jeopardized by delaying the latter for the short time necessary to determine the success or failure of the toxins. In cases of rapidly growing small round-celled sarcoma of the bone, I would not advise the toxins, but immediate amputation.

The Use of the Toxins as a Prophylactic Measure.—I have used the toxins in a number of cases after primary operation, with the idea of lessening the chances of recurrence. Theoretically this use of the toxins has much to recommend it, but as yet the cases are too few in number to justify positive statements. A few weeks' treatment with moderate doses is free from risk, and is, I believe, worthy of trial.

The Method of Preparing the Toxins and Technique of Administration.—The preparation at present used differs in no way from that described in my previous paper. It consists of the mixed, unfiltered toxins of the streptococcus of erysipelas and bacillus prodigiosus, grown together for two weeks and sterilized by heating to 58° C. In children and patients much reduced in strength, it is better to use the filtered toxins. This preparation is much weaker than the unfiltered, the relative strength being about 1 to 10. However much difference of opinion there may be as to the part the bacillus prodigiosus plays in causing the disappearance of sarcoma, the fact remains that all of my own successes, as well as those of other surgeons, have been obtained with the combined toxins, and I am quite convinced that the process of degeneration of the tumor tissue is greatly increased by the addition of the prodigiosus.

Many opinions have been expressed as to the nature of the process by means of which a cure is effected in the successful cases. The opinion which has been most generally advanced—though resting on theoretical rather than practical knowledge—is that it is a simple necrosis or sloughing process, resembling that following the injection of any powerful escharotic, like carbolic acid. Consequently, it has been regarded as an entirely local process. This is far from the truth. While in some cases of soft round-celled sarcoma the rapid breaking down of the tumor would lend support to this view, there are many cases that absolutely disprove its correctness. A number of cases of sarcoma have disappeared entirely by absorption, with no breaking down; and furthermore, in several cases the injections were made remote from the tumor. This proves the action to be systemic as well as local. The toxins in some way, acting probably through the blood serum, cause a necrobiosis with fatty degeneration of the tumor cells, the breaking down and formation of the slough depending entirely upon the preponderance of the cellular elements over the intercellular or fibrous stroma. In the spindle-celled variety absorption without breaking down is the more common process, while in the round-celled type the reverse is true. Usually, when possible, it is better to give the injections locally; a much larger quantity can, however, be safely given subcutaneously than when injected into the tumor, and this is a point of much practical importance. A severe chill and rise of temperature to 105.5° F. have been known to follow the injection of one-half minim of the mixed, unfiltered toxins when made into a highly vascular sarcoma. The severity of the reaction depends largely upon the rapidity of absorption.

Dosage.—The rule should be to begin with a minimum dose—for example, one-half minim—and slowly increase daily until the desired reaction has been reached. If this rule be carefully observed, the element of danger is exceedingly small. Inasmuch as the dose depends largely upon the virulence of the cultures from which the toxins are prepared, and since it is extremely difficult to keep cultures of the same degree of virulence, the dose must vary within certain limits, and can be determined in the individual case only by trial, the temperature furnishing the guide. The initial dose should never be larger than one-fourth to one-half minim; boiled water may be added for the proper dilution. The aim should be to give sufficient to produce a temperature of 101°–103° F. In some of the successful cases not more than three or four chills were produced during the entire course of treatment, and frequently patients have steadily gained weight while under the treatment. This controverts the statement of some writers that the treatment is exceedingly depressing and causes rapid emaciation. This may be true if the doses are too large, but not when the treatment is judiciously carried out. Strychnine may cause speedy death or act as an excellent tonic, according to the amount administered.

[1] Abstract of paper read at the meeting of the American Medical Association in Denver, in June, 1898.

Sterilization of the Skin and Needle.—The strictest precautions should always be taken to guard against infection, for the reason that a patient is unusually liable to infection from other germs while taking the toxins. The skin should be rendered aseptic and the needle be sterilized by being passed through an alcohol flame before and after using.

Duration of Treatment.—It is possible in most cases to tell within a comparatively short time whether or not the toxins are likely to be efficacious. If no improvement is noted at the end of three weeks, there will be little use in continuing the treatment. In many cases marked improvement is seen within a week after the first injection. If improvement occurs, the treatment should be kept up until the tumor has disappeared or until it is evidently again increasing in size.

Dangers.—The question of the cumulative action of the toxins if the treatment be long continued is an important one. The toxins are rapidly eliminated, and that no harm is likely to result from prolonged treatment is evidenced by the following cases:

In one case the toxins were administered steadily two or three times a week for a period of two and one-quarter years; the patient gained ten pounds in weight and remained in perfect health the entire time. In a second case the treatment has been continued, with few intervals of rest, for a period of nearly four years, with no ill effects. I have personally had two deaths from the treatment and I have known of six others in the hands of other surgeons.

Review of Cases thus far Treated.—Out of a total of 140 cases, 84 were round-celled; 21 spindle-celled; 6 mixed; 9 melanotic; 2 chondro-sarcoma; 6 sarcoma, in which the clinical diagnosis was not confirmed by microscopical examination; 12 sarcoma, in which the type of cell was not stated, though the diagnosis of sarcoma was confirmed by microscopical examination. Of the 84 round-celled sarcomata, 35 were more or less improved; 3 disappeared entirely, 1 patient remaining well upward of three years, 1 at present well one and one-half years, and the third well at the end of one year, since which time he was not traced. Of the 21 spindle-celled, 10 disappeared and all the others showed marked improvement. Of the 6 mixed-celled, 3 improved; 2 were unimproved; 1 disappeared and the patient remained well for three and one-quarter years, at the end of which time there was a recurrence in the abdomen, which proved fatal after six months' time. Of the 9 cases of melanotic sarcoma only 2 showed slight improvement, the remainder being unaffected by the treatment. One large chondro-sarcoma disappeared, recurred at the end of seven months, and finally proved fatal; the other was slightly improved. Of the 12 cases in which the type of cell was not known, 6 were improved, 5 unimproved, and 1 tumor disappeared. Of the 6 cases not confirmed by microscopical examination, 2 osteosarcomata disappeared, 2 improved, and 2 remained unimproved.

Summary of Results.—Well over three years, 8 cases; well from one to three years, 9 cases; well from six months to one year, 4 cases; recurred after having once disappeared, 4 cases—2 of these patients died, 2 are still living in good health after further treatment.

Successful Cases Treated by this Method by Other Surgeons.—From published reports and personal communications, I have been able to collect 35 cases of inoperable sarcoma in which the tumor completely or very nearly disappeared as a result of the treatment in the hands of other surgeons. In 26 of these cases the tumor entirely disappeared. Of the total number, 10 were spindle-celled; 11 were round-celled (1 giant-celled); 1 myxosarcoma, and 1 endothelial sarcoma; in 10 cases no microscopical examination was made, though careful examination by a number of surgeons rendered the clinical diagnosis scarcely open to question. In the remaining cases the diagnosis of sarcoma was confirmed by microscopic examination, but type of cell not stated. In addition, in 5 of these 9 cases there was a history of recurrence after operation. Of the 34 cases 9 are now well upward of three years; 9 from one to three years; in 6 cases the disease recurred in other regions of the body at varying intervals of from six months to two years after the disappearance of the primary growth. This latter fact alone—that the disease recurred elsewhere—is sufficient to establish the correctness of the original diagnosis of sarcoma.

Conclusions.—A careful study of my own cases as well as those thus far treated by other surgeons justifies, I believe, the following conclusions, which, I might add, are in almost perfect accord with those recently published by Moullin:[1]

I. A considerable number of inoperable sarcomata, the correctness of the diagnosis of which is beyond question, have entirely disappeared under this method of treatment.

II. A large proportion of these cases have remained free from recurrence more than three years after treatment—the period which has generally been accepted as of sufficient length to justify their being regarded as permanent cures.

III. Different varieties of sarcoma differ widely as regards the manner in which they are acted upon by the toxins. The results thus far show the treatment to be most successful in the spindle-celled variety, one-half of the spindle-celled sarcomata so far treated having disappeared. Round-celled sarcomata yield less readily, although a certain number have been successfully treated. No case of melanotic sarcoma has, up to the present time, shown more than slight improvement.

IV. The action of the toxins upon sarcoma must be regarded as a rapidly progressing necrobiosis with fatty degeneration. This action is not the result of inflammation, nor does it resemble the destructive action of a local escharotic, but it is rather specific in character, exerting a direct influence upon the tumor cells.

V. The specific action is further confirmed by the fact that several tumors have entirely disappeared when the injections were made subcutaneously remote from the tumor.

VI. This method of treatment is attended with a certain amount of risk, unless certain precautions are taken. The chief dangers to be guarded against are: (1) Collapse from too large a dose of the toxins or from injections into a very vascular tumor; (2) pyæmia from insufficient precautions as regards asepsis, especially in cases in which there is a granulating or sloughing surface. (That the risks are small is shown by the fact that in upward of two hundred cases treated personally death was caused by the injections in but two, one of which was so nearly moribund that no treatment should have been begun.)

VII. The use of small doses of the toxins for a short period after primary operation, as a prophylactic measure, theoretically has much to recommend it, and and if proper precautions be observed the treatment should be practically free from risk.

VIII. The action of the toxins of erysipelas upon sarcoma, as shown by clinical results, is in strict accord with the known action of the living streptococcus of erysipelas; therefore the method has a perfectly logical and scientific basis.

I wish to express my great obligations to Dr. B. H. Buxton of the Loomis Laboratory, whose skill and unremitting labors in preparing the toxins have made the results here reported possible.

THE RIGHTS OF THE EXPERT WITNESS. PERSONAL EXPERIENCE WITH THE DIXON DECISION.[1]

BY DENSLOW LEWIS, M.D.,

PROFESSOR OF GYNECOLOGY IN THE CHICAGO POLYCLINIC.

THE opinion of the supreme court of this State in the case of J. N. Dixon *versus* The People of the State of Illinois was filed November 1, 1897. In Illinois, as far as expert testimony is concerned, the decision in this case is now the law, and to a great extent it determines the law of the land. On account of its importance the case has attracted widespread interest, and the details are very generally known to medical men and lawyers throughout the country. Nevertheless, it seems advisable in this connection briefly to refer to its salient points, as well as to the arguments of counsel and the factors which apparently influenced the appellate and supreme courts in arriving at a decision.

In January, 1895, Dr. J. N. Dixon, of Sangamon County, Ill., in answer to a subpœna, appeared in the circuit court as an expert witness. He was confronted with a hypothetical question relating to injuries, of which he had no personal knowledge, said to have been sustained by a woman whom he had never known. He was asked as to the probable result of a fall on a defective sidewalk in producing certain injuries, and, after receiving the assurance of the court that he was called as an expert witness only, he respectfully declined to answer. He explained his refusal to answer "on the ground that an expert witness is entitled to a different and greater compensation than an ordinary witness is allowed, and that an expert is not required to give expert testimony without compensation as an expert, unless a reasonable compensation shall have been paid or provided for." The court held refusal to answer as "conclusive proof of contempt of court and of his disposition to persist in such contempt," and imposed a fine of $25. The doctor's attorney, Mr. Conkling, excepted to the order of the court finding the witness guilty of contempt, and also excepted to the order of the court fining the witness. He filed a motion for the remission of the fine, which was overruled. An appeal was then prayed to the appellate court, which was allowed.

The opinion of the appellate court was filed December 2, 1895. The question at issue is thus stated: "Could the appellant, under the circumstances, lawfully decline to give his professional opinion without reasonable compensation?" It is acknowledged that the question has never been directly passed upon in Illinois, nor "can any rule be drawn from the currents of judicial decisions in other jurisdictions or from a concurrence in the views of text writers." It is further acknowledged that the contention on Dr. Dixon's part is that "the party desiring his professional opinion should be required to compensate him therefor, before the law should compel him to express that opinion for the benefit of such party." The opinion holds that the circuit court ruled correctly in holding that the law required the witness to answer the question. It is stated that the statute has fixed the compensation to be paid all witnesses, and "the law requires every person, when duly subpœnaed, to appear as a witness and accept as full compensation the statutory allowance, however inadequate it may be."

It is held that the administration of justice in the adjustment of the contentions growing out of the business affairs or concerning mere private personal property, is "one of the most important sovereign duties devolving upon the State. This duty can be discharged only through the medium of judicial tribunals, and these tribunals would be powerless to perform their functions if they could not compel witnesses to attend and disclose facts in knowledge pertinent to these contentions." It is further held that no distinction can be drawn between different kinds of knowledge, nor can a witness "decline to make known facts which have come to his knowledge either by observation or study and experience, upon the ground that he can use such facts or knowledge for his pecuniary benefit in the business affairs of life, when the disclosure thereof is important to the attainment of justice in the courts." It is then stated that some books on expert testimony enumerate as many as seventy classes of expert witnesses, and it is asserted that it would subject a litigant to great financial burdens if each member of these different classes of witnesses had to be paid a reasonable compensation "before he could be compelled to disclose in open court facts in his knowledge relating to the right and justice of causes there pending for determination."

The appellate court, in affirming the judgment of the circuit court, takes occasion to state that knowledge gained by study, observation, and experience is not property within the meaning of the word, in the sense that "private property shall not be taken or damaged for public use without just compensation." The word property, it is asserted, means "tangible things and rights which accompany or are incident to the use, enjoyment, or disposition of such things."

In June, 1896, this case came up to the supreme court on a further appeal. The brief of Dr. Dixon's attorneys, Messrs. Conkling & Grout, is a learned dissertation concerning medical expert testimony in the different States. It refers also to the customs of the ancients, and quotes from authorities and practices of almost every civilized country. Their argument is concise and scholarly. They state the fact emphatically that in the case at bar there is no involvement of any question of government, of crime against the laws of the State, or any matter which might be included under the right of taxation or the police power. They say: "A citizen having no knowledge of the facts in controversy, no interest directly or indirectly in the result of the suit, is compelled to yield up without compensation the fruits of his study, skill, and experience, that one of the parties litigant may recover a larger sum of money or that the other may escape the payment of such sum. As well might the farmer, the merchant, or the manufacturer be required to contribute of his property at the call of any litigant who might fancy it would be to his advantage to have it."

They further show that no question of the duty of the citizen to the State is involved, nor is there the refusal of a witness to testify to facts in controversy within his knowledge. There is purely and solely a question of expert testimony which, it is endeavored to prove, is either property or "particular services." Under either view, it is asserted that a citizen under the circumstances in question cannot constitutionally be required to give expert or opinion evidence without full and just compensation being made for the same.

The decision of the supreme court in this case is well known. It was decided that a physician, when subpœnaed and interrogated as an expert witness, may be compelled to testify without pay other than the statutory fee. He must testify in civil as well as criminal suits, since "in either case the object is to promote public justice and insure the peace and good order of society." If he refuses to testify when regularly subpœnaed and placed upon the witness stand, the court is justified in fining him for contempt.

In the opinion of the supreme court, delivered by Mr. Justice Magruder, it is stated that the grounds upon which the right to extra compensation has been sustained are generally three in number: First, it is

[1] Read before the Illinois State Medical Society, May 18, 1898.

claimed that the time of the expert witness is more valuable than the time of ordinary men, and that, by attendance at court to give his testimony, such a witness meets with a loss of time. The opinion is given that any ordinary witness who goes to court and testifies as to facts is subjected to a loss of his time as much as a witness who goes there to testify as an expert upon a mere matter of opinion.

The second ground upon which the claim for extra compensation is based, is that the skill and accumulated knowledge of the expert are his property, and that a man's property should not be taken without just compensation. It is asserted that it is not accurate to say that the mere abstract knowledge, acquired in the study of a special employment, is of itself property. "It is the right to apply that knowledge to the accomplishment of a particular result which constitutes property." If the witness, for example, had been required to answer a question with the view of prescribing a remedy for the woman who was injured, then it might be said, if he was not offered any compensation, that he was deprived of a property right. "But when a physician is asked a hypothetical question, and is called upon to give his opinion upon the facts stated in the hypothetical question while he is testifying as a witness in court, he is not thereby required to practise his healing art. He is merely making a statement, not for the purpose of effecting a cure or relieving a patient, but for the purpose of enabling the court and the jury to understand correctly a case which is before the court."

It is conceded that, in a certain sense, the knowledge of the physician, acquired by special study, is property; but, it is added, "the question here is not so much whether certain knowledge is property, as whether the requirement that he shall answer a hypothetical question is a taking of his property." It is further stated—and right here is the important point in reference to my own experience—that "where he is required to make an application of his knowledge to a particular case, so as to secure a particular result—such as, for instance, the curing of a disease or the healing of a wound—then he would undoubtedly be entitled to compensation. A physician or surgeon cannot be punished for a contempt for refusing to make a post-mortem examination, unless paid therefor, nor can he be required to prepare himself in advance for testifying in court by making an examination, or performing an operation, or resorting to a certain amount of study without being paid therefor."

The third ground for extra compensation is that the accumulated knowledge and skill of an expert witness may be treated as "particular services," and it is explained that, while such a construction of expert testimony may hold good in Indiana, it does not apply to Illinois, because the ordinance of 1787, wherein those words are found, is not in force in this State.

The supreme court concludes by quoting and endorsing the views of the Texas court of appeals as follows: "It is to be regretted that a member of a profession, so distinguished for liberal culture and high sense of honor and duty, should refuse to testify in a case pending before the courts of his country, involving the life and liberty of a fellow-being, and the rightful administrations of the laws of a common country."

Now this is the decision in the celebrated Dixon case. Much might be said in criticism of the opinion of the supreme court, but it is, I suppose, useless to do so now. This decision has become the law, and the duty of every citizen is to obey the law. In fact, he has to do so or suffer the consequences. It is now possible for every pettifogging attorney to call to his aid in the most trivial case in any court the most eminent man in the medical profession. The engagements of such a man are not to be considered. He must leave the most important case to attend the behests of any attorney who may wish to dignify his cause by the presence of some noted physician or surgeon on the witness stand. He will receive one dollar a day and five cents a mile for travelling expenses. His absence may cause him to lose hundreds of dollars, but the "member of a profession, distinguished for liberal culture," etc., will not, of course, take exception to a mercenary matter of this kind. His "high sense of honor and duty" will amply console him. Possibly he may be of a philosophical turn of mind, so that he will duly appreciate the value of an enforced engagement of this kind as an opportunity for enjoying a much-needed diversion.

But I will say no more in explanation or criticism of the Dixon decision. Every medical journal in the country has been up in arms against it. Every medical expert has protested. It is useless to inveigh against it, for it is the law which we must all obey.

Unfortunately, this decision appears to have far-reaching consequences which as yet we have not dreamed of. Not content with depriving the medical man of his fee whenever he is put upon the witness stand by due process of law—that is, by subpœna—if my experience counts for anything, it would appear that this decision is to become the basis for depriving him as well of numerous other rights which other citizens hold under the law of contracts and the principles of equity. Let me relate the details of my case as far as it has gone:

In the summer of 1890 I was called to treat Emlen S. Blye, a woman of uncertain age and unknown antecedents. She was injured in the knee on a suburban train of the Illinois Central Railroad, and suffered severely from her injuries for some little time. While I was treating her, she told me that she intended to bring suit against the railroad company, and asked me to do everything in my power to help her. She said her attorney claimed that she could recover at least two or three thousand dollars, and in that event she promised to see that I was well paid for anything I might do for her.

She wished me to advise with her attorney, Colonel Southworth, which I did on some ten or twelve occasions. We conferred as to the best way to present her case. It was of course evident that if the injury was permanent, it would prevent her from earning her living as a teacher of the Delsarte method, which was her occupation prior to the accident, and consequently she might reasonably claim heavy damages.

I suggested to Colonel Southworth the advisability of having Mrs. Blye consult Dr. Charles F. Stillman, now deceased, but at that time a well-known orthopædic surgeon. My object in this advice was to secure for the patient the benefit of this specialist's skill in the treatment of the injury to her knee, as well as his testimony in her behalf on the witness stand. For several months she was treated by him and by Dr. A. B. Hosmer, associated with him, but without appreciable benefit.

The day of the trial drew near. Colonel Southworth and I deliberated as to the conduct of the case. We considered the advisability of subpœnaing Dr. Fenger. There was, in my mind, a suspicion of tuberculosis. I feared if Dr. Fenger were placed upon the stand the question of tuberculosis in reference to the patient's injury to the knee might be raised, and I questioned the effect of his testimony upon the jury. By my advice he was not called. Dr. Stillman's ill health necessitated the use by him of a large quantity of morphine. I feared the result of a cross-examination in his debilitated condition and advised that Dr. Hilton, who had kindly seen the patient a few times in my absence, should be the only practitioner besides myself who would testify for Mrs. Blye.

In the summer of 1891 the case came to trial. I was not subpœnaed, but was present the first day and gave my testimony as to the facts as far as I knew them. I also gave expert testimony as to the probable relationship of the injuries sustained to the accident which had occurred. I further stated that in my judgment the injuries sustained were permanent.

The second day I received a telegram from Colonel Southworth, asking me to come to court immediately. He thought it probable that medical experts would be put on the stand to controvert my testimony. He wished me to be present to assist him in the examination of these witnesses. On the receipt of this telegram I left everything and hurried to the courtroom. No medical witnesses appeared during the morning session. When court reconvened in the afternoon, I was present and remained in attendance until it became evident that no expert testimony would be offered by the railroad company.

The result in this case, after all appeals had been taken, was a verdict for $9,000, which the patient received, and which at that time was one of the largest verdicts ever sustained in a personal-injury case.

I was absent in Europe at the time Mrs. Blye was paid this money. She wrote my partner for a bill for professional services. This he made out at a nominal figure for all services not connected with her lawsuit, and she paid it. He knew she claimed to be poor, and was ignorant at the time that she had recovered in her suit against the railroad company. I had simply marked the word "special" in our ledger in the space corresponding to the date of her trial, and no bill was sent her for services rendered by me in and about her lawsuit. I confidently expected, when she recovered a verdict so much in excess of her most sanguine expectations, that for the services I had rendered she would gladly give me at least $500.

But, alas, for my confidence in feminine gratitude! In the summer of 1893 I saw Mrs. Blye, like Maud Muller, more or less gracefully raking the grass in front of an apartment building she had built with the proceeds of her verdict. I stopped my horse and complimented her on her own healthful and cheerful appearance and on the substantial character of her building. Incidentally, I made bold to remark that I had not been paid for my services in her case. She now waxed indignant. She said her attorney was everything that was vile, and intimated that I was no better. I remonstrated gently but ineffectually, and left her to her horticultural pursuits.

Subsequently I communicated with her. I sent her a bill for $100 for my services. I wrote her, but to no avail. Finally, in 1895, I sued her before a justice of the peace and secured judgment for $100 and costs of suit. She took an appeal, and on December 17, 1897, the case came to trial in the circuit court of Cook County before his Honor, Judge Richard S. Tuthill. I here secured judgment for $2.20, the statutory fees for an ordinary witness in any case.

Now the proceedings in this case are interesting. My attorneys, Messrs. Church & McMurdy, showed that I gave expert testimony and assisted the counsel in preparing for trial. Mrs. Blye's attorney admitted that I had testified in her suit against the railroad company, that I had not been subpœnaed, but attended voluntarily, and was called as an expert witness. He claimed that I was entitled to nothing but what the statute provides, but he also admitted that if I was entitled to anything over and above the statutory provision I was entitled to $100. I then testified regarding my connection with the case as already narrated, and in answer to a question from the court I said that I considered my services worth $500, but I sought to recover $100 only. It was admitted that Mrs. Blye had received $9,000 after her case was affirmed in the appellate court. She offered no evidence.

My attorneys then asked the court to hold the following propositions of law:

1. That a valid contract may be made with a physician to assist the attorneys in a suit at law in the preparation of the case, whereby the physician is to be given extra compensation therefor.

2. That a valid contract may be made between a party to a suit at law and a physician for the payment to the latter of a compensation beyond statutory fees in consideration of assistance rendered by him to the attorneys of the party in the preparation and trial of the case.

Both of these propositions were held by the court, but the court refused to hold:

1. That the contract in my case was valid.

2. That a person may make a valid contract with a physician by which it is agreed that the physician shall be paid extra compensation for his services in testifying as an expert in a suit at law.

3. That I was entitled to recover of the defendant the sum of $100.

It was further held that I was entitled to receive the sum of $1 for each day's attendance and five cents per mile each way for necessary travel when attending court as a witness, and no more. Judgment was given for $2.20, and I have appealed the case to the appellate court, where my appeal is now pending.

The learned judge seemed much interested in the Dixon decision, which he then saw, as he said, for the first time. He told us that he had nothing besides my case to consider that afternoon, and for our edification, I presume, he read aloud the report of the Dixon decision from a copy of the Illinois Official Reporter, which my attorneys handed him. When he had finished, he announced that there was nothing more to be said. His attention was called to the fact that I had not been subpœnaed, that I had assisted the counsel, and to other facts in the case, but all to no avail. He seemed to take the view that the Dixon decision settled all matters relating to medical testimony, and that the statutory fee must cover all claims of every kind that a medical witness could possibly make under any circumstances in any case.

I cannot consistently or conscientiously accept this conclusion. The sum of money involved in my own case is only $100, and it is doubtful if I receive a dollar of it, even if, in the course of time, the appellate court decides in my favor. I am given to understand that the $9,000 received by Mrs. Blye in 1892 has now been dissipated in one way or another. Nevertheless, I feel there is here a principle at stake, and I believe it to be my duty, under the circumstances, to maintain the privileges of the citizen, which are not sacrificed when he becomes a medical man. I consider that the Dixon decision has been used to abridge my personal rights, both as an individual and as a physician. I therefore consider it but just for me to do all in my power to prevent what I regard as further injustice being done to members of the profession who may happen, in the course of their practice, to act in the capacity of expert witnesses.

The brief filed by my attorneys in the appellate court shows the two questions involved:

1. Where a suit at law involves an inquiry into questions concerning any particular science, as to which the opinions of experts in that science are necessary or competent evidence, can an expert witness, who at the request of a party and upon promise of compensation beyond statutory witness fees has conferred with the attorneys of such party in advance of the trial for the purpose of advising them in reference to the character of his testimony and assisting them in preparing for its proper presentation to the court and

jury, and has then, without subpœna, attended the trial as a witness and given his opinion as an expert upon the matters submitted to him upon the witness-stand, recover from the party employing him the larger compensation promised?

2. Where, in addition to the particular services above described and upon a like promise of compensation, the expert has in advance of the trial consulted with the attorneys for the party employing him, and advised them as an expert generally upon its conduct in reference to the questions of science involved, and attended at the trial for like purpose beyond the time necessary for his attendance as a witness merely, can he recover the larger compensation promised?

Many authorities are quoted to show that expert witnesses should be paid for their services. The radical fallacy of the argument based upon a supposed public duty is clearly expressed as follows:

"That it makes the obligation of the particular citizen to perform the particular duty depend upon his arbitrary selection for that purpose by a private and irresponsible individual, out of a multitude of his fellow-citizens, and by punishing him for a failure to obey that designation virtually places his liberty within the arbitrary and unrestrained control of any one who chooses to exercise it. The process of the court is signed and sealed by its clerk in blank, and delivered to any applicant."

It is admitted that, since the Dixon decision, the question, in the bald form just presented, must be regarded as settled. But, my attorneys add, "it would be manifestly erroneous to burden that opinion with any purpose beyond that which was necessary to the decision of the particular question there before the court, which was expressed in the syllabus in these words, namely: 'A physician subpœnaed and interrogated as an expert witness only cannot refuse to testify upon the ground that no compensation greater than that allowed to ordinary witnesses has been paid or promised to him.'"

The differences between the Dixon case and mine are then stated, as follows:

1. In the Dixon case the expert attended in pursuance of a subpœna.

In my case I attended upon request of one of the litigants.

2. In the Dixon case the witness, being sworn, refused to testify, on the ground that he had neither been paid nor promised extra compensation, and the court held that this was not a valid reason for refusing to testify.

In my case the extra compensation had been promised and the services rendered, and the only question is whether the promise is one which can be enforced.

3. In the Dixon case, so far as appeared, the only service which the expert was called upon to render was to answer the questions asked of him as a witness upon the stand. No preliminary preparation was required, no conference with counsel, no advice to counsel in preparation for the presentation of his evidence to the court and jury.

In my case all of these are essential elements of the proposition.

Now in the Dixon case the court expressly said: "A physician or surgeon cannot be punished for a contempt for refusing to make a post-mortem examination, unless paid therefor, nor can he be required to prepare himself in advance for testifying in court by making an examination, or performing an operation, or resorting to a certain amount of study, without being paid therefor."

So that it is evident that the decision of the Dixon case neither directly nor indirectly controls the decision of my case, except in so far as the paragraph just quoted may be considered to uphold, as it undoubtedly does, my contention.

This all seems very clear to me. I fail to understand how any one can take a different view. My only explanation is that the learned judge before whom this case was tried seems to have fallen into some strange misapprehension concerning the real point involved. He admits that a valid contract may be made between a litigant and a physician, by which it is agreed to pay a physician for assisting counsel in a case, and the undisputed evidence shows that such a contract was made between Mrs. Blye and myself. Nevertheless the court refuses to hold that the contract between us is valid. He rests on the Dixon decision, and appears to think that decision decides everything as far as medical experts are concerned. I venture the opinion that he will not be upheld by the appellate court unless upon some technicality.

Now here is my experience with the Dixon decision. It is not yet complete, but I confess it is a sufficient experience to satisfy me. Much might be said in this connection. I content myself with the expression of but one practical thought. The truth is not what is sought in any law suit. Each side tries to win. The most brutal murderer, if he has means, will retain an eminent attorney to save his neck if possible, and, if not, to secure as lenient a sentence as possible.

It is considered consistent for an attorney, whatever may be his personal ideas on any subject, to act in a professional capacity for any client who can pay for his services. It is well known that few attorneys will refuse a fee from any client, provided it is sufficient in amount. I know an elder in the church near me who is a rabid temperance man, and yet I remember when he defended a saloon keeper who was arrested for selling liquor without a license. I happened to hear him talk to the jury, and I was amused when he asserted that the saloon was the only place where the weary pedestrian could rest. I have a very dear friend who is the attorney for several corporations. He is a Populist—almost a Socialist—and in public addresses he condemns trusts and corporations. In his professional capacity, however, his services are given to the corporations he bitterly and vehemently denounces.

Certain medical men, in their professional capacity, are called upon to do medico-legal work. This is legitimate practice. Indeed, it demands, in some instances, a very high degree of medical knowledge, great perspicuity, as well as perspicacity, and a mind trained in logical reasoning. It is absurd and untrue to say that medical men when called to testify as experts are solely seekers after the truth. It would be as sensible to assert that lawyers in their controversies were actuated solely by a desire to see justice done. Lawyers try cases to win. In certain instances they require the assistance of experts, who may be members of one profession or another, or who may have acquired special knowledge in some department of technology. Lawyers, or the individuals or corporations they represent, employ these experts for their own benefit. They make use of the peculiar knowledge of the expert to further their own ends.

It does not follow that the expert becomes at once a knave and a liar because he is necessarily somewhat partisan. He gives his services to a certain case for a suitable consideration. His peculiar knowledge and his experience enable him to give definite data to the attorneys, upon which they may adopt a line of conduct in their judgment best calculated to win.

I was called on one occasion in a case in which a woman was thrown to the floor of a street car in consequence of some accident to the cable. Six months afterward she submitted to an operation for pyosalpinx. She claimed that infection of the tube had occurred as a result of the accident. The attorneys for

the street-car company called together some six medical men for consultation. They were men who possessed special knowledge in pathology, surgery, and gynæcology, and whose experience was well known. The details of the evidence were laid before us. It soon became evident that a condition such as represented by the plaintiff was an impossibility. We could surely and truthfully say that a pyosalpinx could not develop in a perfectly healthy woman as the result of an accident which did not cause penetration through the abdominal wall, the vagina, rectum, bladder, or uterus. It was conceded that, if the woman was already infected, if she had gonorrhœal salpingitis, for example, it was possible for an accident to aggravate her condition, and it was possible that under these conditions a pyosalpinx might ensue as the result of the accident. We were able to say that, so far as we knew, no case was on record in which a pyosalpinx had developed as claimed, and we were in a position to testify that we had operated in many hundreds of cases of pyosalpinx.

Our advice to the attorneys was to the effect that in their conduct of the case the fact that the woman was perfectly well prior to the accident should be emphasized. We suggested that the usual etiology of such cases in relation to gonorrhœa and abortion should be fully brought out. This was done, and the verdict was satisfactory to the street-car company. The medical experts were paid for their services. Some of them were paid only for the consultation, and others were paid for the consultation and for testifying in court.

Does any one pretend to say that there was here any impropriety, any prostitution of medical knowledge for gain? I contend that it was legitimate for the medical experts to make use of their peculiar knowledge. I hold that the assistance they gave counsel in this case was of material benefit, and that such assistance could be obtained only from duly qualified medical men.

Of course it must be acknowledged that medical men may be dishonest. It does not follow that they become so simply because they give expert testimony or assist attorneys in the preparation and presentation of cases. I was recently asked to testify that no displacement of the uterus could occur by a fall. I was told that several eminent practitioners were prepared to swear to this effect. I at once replied that I could not testify as requested, and my services were not called for in that case.

As a matter of fact, there are disreputable men in every walk of life. It would be unfair to say that they do not exist in the medical profession. At the same time, there is a legitimate sphere of usefulness open to physicians in the field of expert testimony. It is as honorable a specialty as gynæcology or ophthalmology, and it is as unjust to claim that all medical experts are dishonest as it is to accuse all gynæcologists of being abortionists or to class all oculists with itinerants who sell "eye water" throughout the country districts.

It is admitted that the laborer is worthy of his hire. It must be acknowledged that the medical expert is entitled to adequate compensation for services which are often indispensable. The law ought not to prevent a man from collecting what is rightfully due him. The Dixon decision may be the law of the land. It is legal, but no power on earth can make it right. An enlightened public sentiment founded on principles of equity will in time assert itself. The medical expert will then be recognized as an important specialist in the practice of medicine, and his rights will be respected.

217 Fifty-Third Street.

Whooping-Cough.—Inhalation of ozone, for ten or fifteen minutes, twice daily, is recommended by Labbé and Oudin.—*Jour. de Méd. de Paris*, No. 4, 1897.

FIRST HOUR WITH THE MOTHER AND NEWBORN BABY.

By R. OSGOOD MASON, M.D.,

New York.

The instant of birth is certainly an epoch in the life of both mother and child—to one it is the beginning of a new mode of existence; to the other it is the ending of a period fraught with most profound interest and mystery, and culminating with pain and peril. It is an instant which the thoughtful physician, no matter how often he has borne his part in it, always contemplates with the deepest interest and sense of responsibility. If the labor has been speedy and normal, the feeling of responsibility may be measurably diminished; on the other hand, if it has been tedious, replete with uncertainties, and perhaps terminated by operation or instruments, that responsibility is greatly augmented. In either case there are duties of no ordinary importance to be performed, and while these duties have time and again been the subject of discourse by the teachers of obstetrics, aside from the ordinary technique there a few points which my own experience has impressed upon me as being important. They are all doubtless known and practised by some, but they may not all have received the attention which their importance deserves. They do not relate to safety—that, of course, has not been neglected—but to comfort and expediency.

First of all, when the baby is born and the sharp cry has gone forth making certain of life and respiration, let the physician allay the anxieties and fears of all present by his own calm and confident bearing, and also by the assurance that all is well and that there is no occasion for excitement or hurry; thus, if the mother be conscious, she is soothed and reassured. She, however, demands first attention. See to it that shock has not been too great, that pulse and breathing are at a safety point, and that the uterus is contracting: then give attention to the baby. First have the face cleansed with pure, warm sweet oil; then have ready a cup of warm water which has been sterilized or boiled, and thoroughly cleanse the eyes, allowing the water to run freely over and into them: also cleanse the mouth and tongue with pure water.

Then when all is ready deliberately attend to the cord: and here it seems to me the usual technique is faulty. By tying the cord at once while the circulation is still going on, a bulky mass, consisting of the gelatinous covering which surrounds the vessels and the contents of the vessels themselves, is confined and left to desiccate and partially decompose during the next five or six days, before it falls off. A more cleanly and desirable method is as follows: Take up a loop of the cord, six or eight inches from its attachment at the umbilicus, and hold it firmly between the thumb and index finger, compressing the circulation—if it is still going on—in both sides of the loop; then cut the cord in the loop, and the ends thus formed are still firmly held between the thumb and finger, and hemorrhage is perfectly controlled. If the placental end does not bleed, drop it; no hemorrhage of any account will occur; or it can be tied if thought necessary. I never have found it so. Then, loosening the hold upon the umbilical portion, allow the contained blood to escape, and generally all hemorrhage ceases; but, whether it does or not, with a dry towel grasp it firmly and squeeze it thoroughly—pressing out the blood and gelatinous matter, pinching and kneading it, but with care not to make traction upon it—until it is reduced to a mere shrivelled string. All oozing has by this time ceased, but for safety it should be tied an inch or two from the abdomen and the superfluous portion cut off. The child is then delivered to the nurse for cleansing and dressing.

Here, again, it has seemed to me that the usual technique might be improved upon. Instead of the usual scrubbing with soap and water, a cup of warm sweet oil and a piece of very soft muslin or cheesecloth are the only materials needed. With these the sebaceous material so often difficult to remove by washing is easily disposed of, and the cleansing process goes on with ease and comfort to both nurse and child; no water is needed; a yard of cheesecloth or a soft worn towel makes an efficient absorbent for the oil, and the child is ready for dressing. The usual custom of swaddling up the little stranger in flannel petticoats, dimity, lace, and furbelows is both uncomfortable, inconvenient, and absurd; true, the sense of feeling is not very acute, but to subject the tender skin of the newborn infant to all the friction and constrictions imposed by the usual dress is a barbarism to the infant and a trouble to the nurse, necessitating the inconvenient process of hunting up the baby amid its manifold coverings whenever a change of toilet or an inspection by the physician is necessary. Instead of this cumbersome dress, I have a simple wrapper of ample size made of cheesecloth, muslin, fine flannel, or silk, according to the fancy of the mother—either cheesecloth or China silk is suitable—and this well lined throughout with absorbent cotton, and lightly tufted to keep it in place, completes the garment. A pound package of the cotton is more than sufficient for the lining. Diaper and a light belly band are adjusted, then the baby is enveloped in this warm, soft garment, and over all the usual soft flannel blanket is wrapped, and the child is dressed. It reminds one of a young bird in its feather-lined nest, and I have called it the bird's-nest baby dress. Mothers often continue this dress for their infants several months. From two to half a dozen of these garments should form a part of the baby's outfit, and the cotton lining may be in part or wholly renewed as occasion may require.

While this process of dressing the baby goes on, the physician again gives attention to the mother. When the removal of the afterbirth has been accomplished, contraction of the uterus secured, and any necessary repair of the perineum made, the application to the vulva and perineum of towels wrung out in hot water is most grateful and helpful to the patient, and he who has heard the expressions of relief and thankfulness elicited by this simple procedure is not likely afterward to forget or neglect it.

The bandage, though discarded by some, seems to me perfectly physiological in its action as a temporary support to the relaxed and weakened abdominal muscles; and here also the comfort expressed by the patient adds weight in favor of its use.

One point more, though not a care of the first hour; it is a matter of so much importance and one not always given due consideration, that I will venture to allude to it. I refer to the care of the breasts.

There is no one thing in the medical practice of twenty or thirty years ago that I look back upon with such horror—unless it be the treatment of the eruptive diseases and diphtheria in children—as the treatment of the breasts of the lying-in woman. Rubbing, poulticing, a variety of hot applications, and the knife constituted the chief routine treatment, and the agony endured by the patient was horrible to contemplate. Even now, if one is so unfortunate as to meet with a specimen of the genuine old-time nurse, he may be obliged to resort to threats of immediate and ignominious expulsion before he can put a stop to similar work. Vigorous rubbing, hot oil, and an abundance of greasy flannel are the means employed, without a thought that any other course should be pursued. An immediate removal of the flannel or poultice, a gentle but thorough cleansing of the indurated and inflamed breast with tepid water and soap, and the application of a muslin bandage snugly but gently and smoothly from axilla to navel, sufficiently tight to give entire support and gentle pressure to the breasts, elicits such expressions of relief as are not soon forgotten. The milk soon makes its appearance, and a little slit or opening is made in the bandage to liberate the nipple. This procedure, and sometimes the judicious use of a well-covered ice bag, saves nine-tenths of cases which would otherwise result in abscess.

THE RODS AND EPITHELIAL PIGMENT LAYER OF THE HUMAN RETINA CONSIDERED AS A PHOTOCHEMICAL OR SENSITIVE PLATE.

By FRANK P. PRATT, M.D.,

JOLIET, ILL.

In a paper published in the Medical Record, August 28, 1897,[1] the writer endeavored to show that the histological arrangement of the various retinal layers, together with the behavior of light rays under the influence of the ocular refracting media, points to the tenth or pigment epithelial layer as being the sensitive plate upon which images of external objects are reproduced in all their colors, and from which the cones alone receive light stimulus. The rods were there assumed to be essentially a part of the tenth layer, and not terminal percipient cells of the optic nerve; their main purpose being to support and maintain the cones in their normal position at right angles to the external limiting membrane and the pigment epithelial layer, where, in the extrafoveal regions, they are no longer able to support each other. It is now my purpose to offer additional evidence which apparently corroborates this hypothesis. It will be recalled that the first retinal layer lies in apposition to the vitreous body, and the tenth approximates the choroid coat; that the ninth is the layer of rods and cones, which have their summits pointing not toward the source of light, but backward toward the epithelial layer; that the rods are immovably fixed, their "gnawed-off" ends forming a close union with the base of the cylindrical cul-de-sac of the epithelial cell in which they are invaginated; that the cone end is free and moves backward or forward under the absence or presence of its normal stimulus.

That there is a decomposable photochemical visual substance in the retina, as represented by the visual purple or rhodopsin of Ball, will not be denied. Solutions of this complex substance have been prepared under the light of a sodium flame; it is a beautiful clear purple solution, very subtle, quickly decomposed by daylight, passing through the various spectral shades until it becomes colorless. Experiments have shown that rhodopsin is normally secreted by the pigment epithelial cell. To say that this photochemical substance is found exclusively in the rods is true only when speaking of the layer of rods and cones; it is present also in the tenth layer. That the rod ends become, physiologically, a part of the pigment epithelial layer, can be possible only through the presence in both of the same photochemical sensitive rhodopsin, or some modification of it. This becomes evident through the experiments of Kuehne and others, which prove that images thrown upon the fundus oculi, when well defined, leave photographs or optograms upon the layer of rods, through the photochemical action of rhodopsin, and this is accomplished only when extreme care is used in shutting out daylight, to prevent bleaching. It appears, then, that without visual purple or some modification of it in the rod ends no optograms can be made. Mays says: "Any matter to

[1] "What are the Functions of the Rods and Cones and the Pigment Epithelial Layer of the Human Retina?"

be rightly called visual matter must lie in a situation where there is reason to place the excitation by light, *i.e.*, in the visual cells. It must also be proven that this matter can be altered by light during life, and that a slight transformation may be of great significance."

In the light of the present theory, Mays' statement must be modified, in that the visual substance (rhodopsin) should not be located in the visual cell, but in the sensitive plate, *i.e.*, the rods and epithelial cells, where, by decomposition, light vibrations are changed into visual stimuli. In speaking of the tenth retinal layer, it must not be supposed that the line of demarcation between it and the ninth layer is sharply defined; indeed, the inner zone of the epithelial cell sends out "indefinite protoplasmic processes," which extend between the rod and cone elements nearly or quite to the external limiting membrane; when light is excluded from the retina these processes are free from pigment, except near their base; when stimulated by light, the fuscin passes along the processes between the rods and cones until the outer segments of the rods are buried in pigment.

It is not unreasonable to conclude, in the light of the above facts, that the sensitive plate of the retina, when excluded from the decomposing influence of light, soon reaches a state of saturation, after which the cell activity becomes latent and the pigment recedes toward its base. In other words, the cell is at rest. Under the influence of light, this photochemical substance or visual purple is being continually decomposed, and, were it not at the same time being actively regenerated, would soon become completely bleached and the retina rendered non-sensitive. The metabolic force in the epithelial cells, therefore, is increased. The fuscin advances along the processes, rhodopsin is secreted, the cell is active. No doubt Dr. Noyes expresses the consensus of opinion in the following sentence: "It is natural to imagine that this remarkable substance [visual purple] has an important relation to sight, but we cannot define its functions, because it is wanting in the cones, which give the best vision." This is a legitimate and it might be said the only conclusion to be drawn from a belief that the rods are, in common with the cones, the terminal visual cells of the optic nerve. Yet if one accepts the hypothesis that the rods are not visual cells, but are primarily supporting-tissue to the cones, and secondarily are physiologically identical with the inner zone of the epithelial cells, and form with the latter the sensitive plate—this obstacle to the definition of the function of rhodopsin is no longer valid. While there are no rods in the region of the fovea, it does not follow that there is no rhodopsin. The physiological function of the hexagonal epithelial cell is as active here as elsewhere, and the visual purple will be found saturating the inner zone of the secreting cell exclusively over this region.

Kuehne's experiments, which prove that animals whose retinæ have been bleached not only can see, but can distinguish colors, do not weaken this argument, because he does not destroy the function of the epithelial cell. Bleaching of the rods alone will not destroy vision for white light or colors, because the rods form a part only of the sensitive plate, each part of which contains the same photochemical substance and upon which, separately or together, colored images will appear. That visual purple is not found in the cone cell is the strongest proof that the function of this cell is not to convert vibrations of luminous ether into nerve stimuli. This function belongs exclusively to the sensitive plate. The cone is sensitive to the converted nerve stimuli only, and conducts them through the medium of the nerve fibre to the cerebral visual centres. It will not be denied that rhodopsin is sensitive to all forms of light, white and colored. The persistence of the positive after-image for a short time after light is excluded from the eye, followed by the negative image in complementary colors, points to photochemical action; the positive image showing a momentary continuation of photochemical decomposition, the negative image showing a reproduction of certain chemical elements which were decomposed by the action of light rays. As soon as the plate reaches its normal degree of saturation, its chemical equilibrium, the after-images disappear. It would seem, therefore, that both chemical decomposition or bleaching of rhodopsin and the regeneration of the decomposed elements produce that subtle stimulus which alone is capable of exciting the terminal cell of the optic nerve.

It has been claimed that Purkinje's phenomenon, in which the shadows of retinal vessels and capillaries can be seen entoptically, proves that the rods and cones are the percipient light structures. In a paper published in 1897[1] the writer has presented conclusions drawn from a long and careful study of entoptical shadows. Attention was called to the appearance of the macula and foveal region, the surface of which is covered with exceedingly fine lines, closely resembling the delicate tracings on a diatom. This tessellated arrangement presents the same appearance as that shown by a surface view of the cones of this region. In view of these peculiarities, and having in mind also the modified histological arrangement of the retinal layers over this region, it was assumed that these tracings represent the shadows of the cones cast upon the sensitive plate beyond. If this is true, it of course adds great weight to the arguments advanced in this paper, and disproves the conclusions drawn by Purkinje.

It will also be recalled by those who have studied the phenomena of after-images that one looks upon them as something apart from himself, as he would look upon a landscape or a picture, and that often some detail will clearly appear in the negative which had entirely escaped the notice before. This fact emphasizes the deduction that not only has photochemical action taken place in the sensitive plate, but that the sensorium takes note of the stimulus as originating, not in its own termini, but in something outside of itself. In view of the above facts, it becomes evident that if the rods and epithelial cells are to act in common as a sensitive plate, the cells must secrete a photochemical substance which they impart to the rods, where they exist, and to the inner zones in those parts where, as in the fovea, the rods are absent. It also becomes equally clear why the cones, whose sole function is to take up nerve stimuli, are not supplied with visual purple.

In addition to the facts already adduced in a previous paper in support of the proposition that the main function of the rods is to sustain the cones in their normal position, the following fact has peculiar significance. Cajal has shown that the Müllerian fibres which constitute the sustentacular tissue of the retina do not extend through the entire thickness of the retina, as claimed by Piersol, but terminate externally in delicate cylindrical cul-de-sacs, into which the bases of the rods and cones pass. These delicate septa extend an exceedingly short distance into the ninth layer; beyond this point the fibres of Müller are not found. Why not? Because here the terminal nerve cell is so surrounded by the protoplasmic processes from the epithelial cells and so sustained by the rods that the latter serve not only as modified sustentacular tissue, but as a sensitive plate as well. But it will be claimed that the rod has been demonstrated to be a terminal nerve cell; if not by continuity, by contiguity.

[1] "What are the Muscæ Volitantes? An Entoptical Study."

Be that as it may, it is claimed here that there is no evidence which proves the rod to be a terminal visual cell. Whatever other connection it may have with the central nervous system is not under discussion in this paper.

A MODIFIED HUTTON'S APPARATUS FOR VALVULAR DRAINAGE OF PLEURAL EMPYEMA.

By R. VAN SANTVOORD, M.D.,
NEW YORK.

A GLASS tube, three-eighths of an inch in diameter, is bent at a right angle. One arm, which is just long enough to reach into the pleural cavity, is thrust through a small hole in the middle of a piece of rather thick rubber tissue, four inches square, which is securely fastened to the tube by winding a few turns of strong linen thread over the projecting lip of the rubber where perforated. The other arm, which may conveniently be about one inch in length, terminates in a valve, which may be extemporized as follows: A piece of rubber tissue, two inches long, is folded around a strip of cardboard, three-eighths of an inch wide, snugly at one end but flaring out at the other. The overlapping surfaces and the three triangular areas on either side of the strip are then stuck together with rubber cement. Over this valve when in use is fastened a loop of sheet zinc to protect it from pressure. A more elegant but not more effective valve can be constructed by any instrument maker. When the tube is in use, a sheet of gutta-percha tissue is inserted between the rubber flange and the chest wall. Gutta-percha tissue, when soaked in a disinfecting solution to render it aseptic, is sticky and unmanageable. If pieces cut to the size required for use are inclosed in a fold of gauze while soaking, and are then placed on a layer of gauze while they are being adjusted to the tube, they may be handled with little difficulty. The rubber is covered over with several layers of gauze, and the whole kept in position by a piece of thin rubber sheeting, through the middle of which the drainage tube passes and which is edged with rubber adhesive plaster. To this plaster are pinned three strips of bandage, which pass around the chest and are drawn tight enough to cause a moderate amount of elastic compression. Absorbent material is wrapped around the valve and its shield, to catch the discharge as it comes out. This apparatus allows the free exit of pus and air, but prevents the ingress of air, as the surfaces of the valve come in contact on inspiration. The result of this is that the patient evacuates the air from the pleural cavity while coughing and the lung expands.

The original apparatus, described by Dr. W. M. Hutton in *The Lancet*, i., 1897, p. 375, differs from the above only in that the glass tube is fitted into a piece of rubber drainage tubing at the end which perforates the chest, and the rubber flange, of rubber sheeting one-sixteenth inch thick, is cemented to this rubber tube. A piece of drainage tubing about six inches long is interposed between the glass tube and the valve. I consider the naked glass tube better than Hutton's arrangement, because it cannot be compressed by granulations, and therefore keeps the drainage opening adequate. Its introduction during the later stages of the case, when the opening tends to close, is therefore much less distressing to the patient than is the rubber; in fact, is absolutely painless. Hutton found that the apparatus was efficiently retained in place by domett bandages and cotton pads. The elastic bandage added by me seems to make it more secure, though it may not be necessary. I dispensed with the rubber tube between the glass and the valve, because it was easily dragged on and was a source of discomfort to the patient.

I have had experience with this apparatus in one or other of its forms in three cases. In the first the apparatus, constructed exactly as described by Hutton, was tried rather late in a case operated on by a colleague at the Harlem Hospital. Its efficiency was demonstrated, but for various reasons its practical value could not be estimated. A second case was admitted to my service at the Harlem Hospital in a moribund condition. Aspiration for immediate relief was performed, followed by exsection of a portion of the middle of the sixth rib and the making of a free opening. An extemporized apparatus practically identical with Hutton's, with the addition of the above-described elastic band, was used, and worked perfectly. Large amounts of pus were discharged into the bottle in which the valved tube entered, and the lung expanded rapidly. The apparatus, however, seemed to distress the patient, possibly owing to the occasional dragging of the bottle, which it was difficult to keep fastened to his body, or to the interference with respiration in consequence of the elastic compression of the chest. As the man was an Italian, speaking no English, it was not possible to find out just what troubled him. After improving for twenty-four hours, his temperature again shot up; he sank rapidly, and died forty-eight hours after the operation, apparently from sepsis. No autopsy could be obtained. It seems possible that in this case the expansion of the lung may have been too rapid, interfering with drainage. It would probably have been better to leave the opening absolutely free until the pleura was in a more healthy condition, though death in parallel cases is not uncommon with free drainage.

My third case, that of a boy of seven, came into my hands two months after the beginning of his illness, said to have been a pleurisy. The effusion extended up to the third rib in front. About one and one-fourth inches of the middle portion of the sixth rib was excised under chloroform and the thorax freely opened. About a pint of pus mixed with large fibrinous coagula was evacuated. The cavity was irrigated, at the time of operation only, with boiled water. The lung was adherent behind. The cavity was felt to be coated with fibrin. In view of the previous case, it was considered advisable to employ open drainage until the fibrinous coating of the pleura had loosened or melted away, and the lung might be forced to expand without fear of forming pockets of retained pus. The temperature became normal at once, and the boy's appetite became ravenous. Hutton's apparatus, with the addition of the elastic bandage, was used at the end of a week for two days, but was then discontinued, as it became obstructed by coagulum. The long tube coming around in front of the abdomen, with its wad of dressing, was a source of discomfort to the patient, and the compression of the thorax by the elastic band caused some dyspnœa. Thirteen days after the operation the apparatus as described at the beginning of the paper was applied, and proved to be perfectly comfortable after the boy became used in the course of a day or two to the elastic band. A thick wad of cotton was bandaged to the chest wall behind the tube, to prevent pressure upon it. He would run about, use his arms, or roll over in bed in any position with absolute freedom from any discomfort. In sixteen days the lung was fully expanded, though a small amount of watery pus was still discharged. The tube was finally removed on twenty-sixth day after operation, the sinus apparently being absolutely closed the next day, though a few drops of pus appeared on the dressings for a week later. It could probably have been safely left out some days earlier.

This was a case that would probably have done

well under open drainage ultimately, but it demonstrated to my mind the efficiency of the apparatus, and in my opinion by its use the cure was materially hastened.

Hutton reports one case in which the discharge ceased and the lung was fully expanded four days after operation.

Progress of Medical Science.

Suprarenal Extract in Addison's Disease.—At the meeting of the Hospitals Medical Society held in Paris on February 25th, M. Becliere showed a young man suffering from tuberculosis, but without any marked pulmonary lesions. In addition he had at one time the symptoms of Addison's disease, but he had lost all these in a short time and had remained free for three years. The chief point of interest in this case was that the patient had been treated with suprarenal extract administered in various ways, given both internally in capsules and in the form of a watery glycerin extract which was injected under the skin. The suprarenals used were those of the calf. Nothing of note happened during the treatment, and it was reasonable to suppose that the giving of the suprarenal extract had contributed very largely to the cure of the patient. M. Becliere compared the treatment of patients suffering from Addison's disease by suprarenal extract with that of patients suffering from myxœdema by thyroid extract, and came to the following conclusions: In myxœdema the beneficial action of the thyroid extract is obvious after only a few days' treatment; in Addison's disease, on the other hand, at least two months elapse between the commencement of treatment and the appearance of beneficial results. In myxœdema the benefits are only temporary, *i.e.*, the patient must continue the treatment throughout the remainder of his life. In Addison's disease the benefits of the treatment last for some five months after the administration of the extract has been left off, and in the case cited the improvement must not only have continued but must have really increased, for the patient had remained well for three years. The fundamental differences between the mode of action of suprarenal extract and the thyroid extract were as follows: Thyroid treatment acted by supplying the organism with substances which the myxœdematous person could not manufacture for himself, while in the case of suprarenal extract the most reasonable hypothesis seemed to be that it brought about a compensatory hypertrophy of those portions of the suprarenal capsules which remained healthy, and this hypothesis agreed with the results obtained by hypodermic injections of suprarenal extract in animals. M. Gaillard said that he had tried this treatment in an analogous case and had obtained no result whatever. M. Widal had tried it in a patient who presented a typical case of Addison's disease, and who had a tuberculous family history. He could tolerate from ten to twelve grams daily of suprarenal capsules of the sheep. No alteration occurred in the amount of pigmentation. The patient left off treatment highly delighted with the increase in his strength, but returned at the end of some weeks just as weak as before, and with gastro-intestinal troubles in addition. He died shortly afterward. M. Widal, however, believed that the treatment was worth trying, provided that it was quite early in the disease. M. Hayem had treated a patient in 1894 with doses of from ten to fifteen grams of calf's suprarenal capsules *per diem*. As in M. Widal's case, the weakness was much relieved after two or three months' treatment, but no difference was noted in the pigmentation. The improvement lasted for ten months, but finally gave way and the patient died in 1896.—*The Lancet.*

The Accidental Ingestion of the Eggs of the Common House Fly.—The ingestion of the eggs of the house fly, deposited in the hot summer weather on meat, cheese, and other articles of food, occurs no doubt more often than we suspect or are willing to believe. If the alimentary canal is in its normal state, no harm comes from such an accident; but if, on the other hand, there is some disturbance of digestion, it is quite possible that these eggs may pass through the intestinal tract uninjured by the gastro-intestinal secretion, or may develop into larvæ within the human body. In the *Deutsche medicinische Wochenschrift* (No. 8, 1898) two such instances are reported. Dr. Michael Cohn, of Berlin, describes the case of a five-months-old child, bottle fed, suffering from dyspepsia, in the vomited matter and in the stools of which large numbers of eggs were found. These soon developed into larvæ in the stools and in the soiled clothing. An examination by the Berlin Zoological Institute demonstrated that the eggs were those of the common house fly, the Musca domestica. The other case is reported by Dr. Bachmann, of Hanover. A gendarme, affected for several years with stomach trouble, and of late in the habit of eating large amounts of chopped meat, both fried and raw, complained that after a preceding period of nausea and cramp-like pain in the pit of the stomach, he frequently vomited large numbers of worms, always more than a hundred. He also observed a number of times "worms" in the stools. An examination of the specimen brought by the patient showed that the "worms" were really the larvæ of flies.

New Joints.—At the meeting of the French Academy of Sciences, held in Paris on May 31st, M. Ollier presented a report on the formation of articulations between bones which are in the normal condition independent of each other, the necessity for so doing having arisen from the natural articulations of such bones having been irretrievably destroyed. M. Ollier has succeeded in making joints possessing both strength and freedom of motion between bones which are not under ordinary conditions connected with one another. In thus reuniting the bones it is possible to preserve not only the tissues which form the junction, but also all that remains of the muscles which moved the original joint, and, in fact, to form a new joint (nearthrosis) surrounded by muscles sufficiently powerful for active exertion. M. Ollier reported the case of a man who was in his forty-eighth year in 1893, and who had received a gunshot wound in 1870. The wound healed after seven months, but opened again in 1883. Successive resections were made for the purpose of checking the suppuration, the head of the humerus being removed in 1884, a portion of the scapula in 1885, and the remainder of the bone in 1890. The suppuration stopped, but the arm was powerless and tended to fall lower and lower from the clavicle, to which it was attached (and that only in front) by some muscular bundles which were not strong enough to raise it. In 1893 M. Ollier fixed the humerus to the clavicle and surrounded the approximated ends of the two bones with what remained of the scapular muscles, which eventually, the deltoid especially, acted powerfully on the new joint. After the operation the patient had no need of artificial supports and used his arm for every purpose required. For instance, he could put it on the top of his head, on his right shoulder, behind him, on the back of his right thigh, and could also fold his arms—movements which were impossible to him before the operation.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 27, 1898.

WOUNDS OF THE THORACIC DUCT.

IN the *Annals of Surgery* for June of this year, there is a paper by Cushing, of Johns Hopkins Hospital, upon wounds of the thoracic duct occurring during the course of surgical operations. A number of cases are quoted, and one which the author treated is commented upon at length. The treatment was by suture and resulted in cure.

The importance of the subject is considerable and is becoming more so, as our operative fields are becoming more and more extensive, especially in malignant disease of the neck or in cases of secondary growths after removal of the breast, since anatomical appearances are apt to be altered under such circumstances. Furthermore, as in Cushing's case, an abnormally high position of the duct is not uncommon, and it is then much more exposed to injury during operation. In all cases in which the duct has been wounded and not repaired, the observer has seen extremely rapid loss of weight with accompanying emaciation and almost always early death, so that prompt treatment becomes of very great importance.

Some operators have been successful in stopping leaks in the duct by using packing in the wound and treating it by the open method. In such cases the wound must have been comparatively small, and the healing process one of adhesion between the lips of the cut in much the same way that peritoneal surfaces adhere. In some cases the possibility of a favorable result may have been made greater by the presence of more than one lymph vessel entering the veins or even a delta-like arrangement. When the latter condition exists and can be made out, there would of course be no objection to a simple ligature of the two ends of the wounded trunk. If the wound in the duct is a longitudinal slit, closure by suture would undoubtedly be the choice of many, for the same reasons that many surgeons prefer to suture a wound in a vein if possible, rather than use some other method.

In the *Deutsche Zeitschift für Chirurgie*, No. 33, 1892, Niebergall discussed very thoroughly the subject of the treatment of wounds of the large veins, and came to the conclusion that the use of suitable clamps applied so as to hold together the edges of the wound in the vessel wall, and left in place for from twelve to forty-eight hours, constitutes a very safe and simple method of handling such cases.

Wounds of the thoracic duct are very perfect analogues of wounds of the large veins, and methods of treatment suitable for one would be suitable also for the other. The thoracic duct is, of course, of very much more importance than a vein of the same size, and when the vessel is wounded or divided that method of treatment ought to be adopted which is the safest, even if it is temporarily inconvenient. Most wounds in the neck in which the duct has been injured will have to be treated to some extent as open wounds, and if we can hold the edges of the slit in the vessel in contact by means of one or more suitable artery clamps, and allow them to remain in place for twenty-four or forty-eight hours, we have a very convenient and rapid method of closure. The introduction of sutures would be very difficult in many of these cases, owing to the small size of the vessel, and would also be uncertain in its results. Furthermore, the application of clamps would reduce the calibre of a vessel and distort it much less than the employment of sutures.

A complete division of the duct in subjects with only one main trunk is a very serious condition, and any treatment is apt to be exceedingly difficult and unsatisfactory. If the end of the duct could be properly isolated, it might be feasible to introduce it into the side of a vein, but this would be a matter of some difficulty and danger, and the absence of valves at the mouth of the duct would be a disadvantage. The control of hemorrhage during such an attempt ought not to be a matter of much difficulty, and it ought also to be possible to keep air out of the veins, though the vein would necessarily be the jugular near its junction. However, any reasonable prospect of success ought to encourage us in a condition clearly so grave. We cannot simply tie the wounded vessel and trust to the right duct to do the work, even when this exists, for it cannot suddenly accommodate itself to such an increased demand, and the danger of rupturing the receptaculum would be great.

MEDICINE IN RELATION TO LIFE INSURANCE.

AN address on the above subject was given by Dr. Muirhead at the meeting of the British Medical Association, recently held in Edinburgh. After referring to the enormous advances the business of life insurance has made in late years—the liabilities of life companies in the United Kingdom amounting at the present time to $1,319,148,125—the speaker proceeded to define briefly the position of the medical profession with regard to the examination of candidates for life insurance. It seems that in Great Britain, up to the year 1830, the societies were content with the perfunctory reports, supplied by any medical man, as to the health of applicants, but that in that year it was deemed prudent to retain the services of a physician to aid in the sifting of cases. In 1835 the companies went a stage farther, and required appli-

cants to appear before one of their own medical advisers, as well as to produce answers to a more elaborate set of questions in respect of health and family history addressed to the private medical attendant. The process of selection of healthy lives has now reached to such a degree of severity that it is almost impossible for a person who is in any way unsound to hope to be admitted to the benefits of life insurance in one of the large companies.

The belief, however, is widely prevalent that all this care is of little avail, and that after five or six years the benefits of selection are entirely lost. The fallacy of this reasoning has, as Dr. Muirhead shows, repeatedly and effectively been exposed. It has been pointed out, however, that, after elimination of the voluntary withdrawals, the advantages of selection diminish at all ages with duration of the policies, rapidly in early life and slowly at middle life; but even in those of advanced years they probably never entirely disappear.

There is another problem in connection with life insurance which is constantly brought to the notice of medical men, and which is far more difficult of solution than that of selection; namely, how to assess equitably the value of under-average lives. In reference to this, Dr. Muirhead says that "here we have no fixed and mathematically correct data by which to guide our decisions. We have no aggregated groups of persons suffering from the same disorder, though perhaps differing greatly in form, which might supply a basis by which to adjudicate upon the special case before us. And if the extra rate recommended by medical officers has in the past saved the office from loss, I am bound to admit that this happy result has been arrived at without the aid of any scientific formula and by merely empirical methods."

The remedy suggested for this state of things is to gather data sufficient to guide physicians in their estimate of extra risks, and to place them in a position to supply the actuaries with statistics upon which to calculate by how much the expectation of life of unhealthy men is diminished in special groups of disease. If this suggestion were successfully carried into effect, it is argued that the task of medical examiners would be greatly simplified. Many applicants are now refused by most companies who will in all probability live longer than many who are passed by the medical examiners. This is especially true in cases of heart affections. A man whose heart or pulse deviates in any degree from the normal, and who has a pulse rate persistently above 90 or below 60, or has habitual arrhythmia, is now rigorously excluded; but it is perhaps unwise to shut this class out altogether, and the fairer course would be for all companies to establish under-average ratings. Tachycardia of 90 or 100 is often due to the excitement of the examination, to tea, coffee, or tobacco; or it may be natural to some persons, and certainly in a considerable number of cases it is not owing to organic trouble. Again, a cardiac murmur is a symptom to which too great importance is often attached; its intensity also is no sure criterion of its gravity. Men are frequently accepted who are to all appearances pictures of health, who yet die suddenly of heart failure, and who are found to have been suffering for years from organic disease. There is certainly room for a revision of the regulations now existing in the conduct of medical life-insurance examinations.

WILL THE SURGEON-GENERAL SUCCEED IN OBTAINING A COURT OF INQUIRY?

We are happy to learn that Surgeon-General Sternberg has demanded from the secretary of war an investigation of the numerous charges of neglect of the sick and wounded during the late campaign, with the view of fixing the responsibility of wrong-doing upon the actually guilty parties. This is the course the Medical Record has urged from the first, as the only means of vindicating the medical department of the army. No explanations yet made have covered the essential points in the scandal. The only way to settle the questions at issue is by a thoroughly impartial court of inquiry and the wide publication of its verdict. Such an inquiry should cover not only the cases of neglect on the battlefield, but also those in our various home camps. It is too late to stave off further discussion by dodging facts, by impugning motives of criticism, and by accepting testimony from interested and necessarily biassed witnesses. Either the facts must be brought out in a perfectly straightforward and legitimate way by a properly empowered tribunal, or, failing this, the public and the profession must be left in grave doubt. But for the good name of the surgeon-general, for the credit of his corps, and for the honor of the profession, we cannot afford to have any doubts in the matter. We have every hope that General Sternberg will be able to defend his course on all the points in the public indictment, and will have the opportunity of proving to the satisfaction of all that he did the best that could have been done under the circumstances. Even if the worst case is proven, we can at least have a grim satisfaction of benefiting in future campaigns by the failures of the past one. We trust the report that the inquiry is to be held is based on something more than a newspaper statement.

THE LIMITS OF HYPNOTIC INFLUENCE.

A case of an interesting nature to the medical profession, and particularly to those members of it who concern themselves with hypnotism, has recently occurred in England. An old lady of the name of Howard died in December last, bequeathing by will to her physician, Dr. Kingsbury, the substantial sum of $150,000. This will the son of the dead woman has been trying to have set aside, on the grounds that she made it under the influence of hypnotic suggestion. It seems that Dr. Kingsbury is a well-known hypnotist and an authority on the subject—so much so, indeed, that he has written a widely read work on hypnotism. The trial, which was remarkable for the number of distinguished British medical men called as witnesses on either side, ended in a verdict upholding the will, the jury finding that it is not within the power of a hypnotist to in-

duce a person in a hypnotic state to perform an action to which he is averse in a normal condition. Unfortunately the evidence of the experts threw but little light on the question of how long the influence of hypnotic suggestion lasts after the hypnotic trance is over. However, whether the verdict arrived at by the jury in the case just decided in England will meet with the concurrence of those versed in the science of hypnotism or not, is doubtful; but, taking into consideration the facts of the case, we imagine that most persons endowed with common sense will be of the opinion that Dr. Kingsbury has been fortunate to be allowed to retain the money left to him. Mrs. Howard was an old lady, seventy-four years of age, who had been in failing health for some years, and therefore was apt to be easily influenced by her medical attendant. The French law dealing with such cases, and which forbids the doctor who attends a deceased person during a last illness from benefiting except to a small extent in any property left, is a wise one. After all, a medical man is fallible, like other mortals, and it is best that temptation should not be thrown in his path.

News of the Week.

The British Vaccination Bill.—A bill was introduced some time ago into the British Parliament, the design of which was to render the vaccination law more stringent in some of its provisions and to introduce some improvements in the methods of public vaccination. Unfortunately a rider in the shape of a "conscience clause" was attached to the bill, and the result is that now vaccination is no longer compulsory. The following is the clause: "No parent or other person shall be liable to any penalty under section 29 or section 31 of the vaccination act of 1867 if within four months from the birth of the child he satisfies two justices in petty sessions that he conscientiously believes that vaccination would be prejudicial to the health of the child, and within seven days thereafter delivers to the vaccination officer for the district a certificate by such justices of such conscientious objection." If false beliefs conscientiously held are to be allowed to stand in the way of the safety of the community, then there is an end of all sanitary legislation. A person who is allowed to refuse vaccination on conscientious grounds may refuse to isolate a patient with small-pox, and the State cannot consistently force him to do so. And this in the country of Jenner!

The Plague in an English Port.—Some consternation was felt by timid folk in London recently upon the announcement that steamer with a case of plague aboard had arrived in that port from Bombay. According to the *British Medical Journal*, this vessel left Bombay on July 2d, taking on board a native crew. As is the practice, this crew was inspected by the port sanitary authority at the time of signing on, and no trace of illness was found. On July 6th a Lascar fireman complained of pain and swelling in the right groin, and stated that his indisposition dated from the second of the month, the day of sailing. On examination the right femoral glands were found swollen, and on the following day the glands in the left femoral region and in both axillæ became enlarged. This case was at once diagnosed by the ship's surgeon, and the patient was placed in one of the ship's boats furnished with an awning and swung out over the lee quarter. Two natives were set apart as attendants. On arrival at Aden a steam disinfector was obtained, all the crew's effects were disinfected, and the patient was landed on an island reserved for infectious cases. The boat was cleaned out, disinfected with 1 in 20 carbolic acid, and repainted. On July 14th another fireman was taken ill with exactly similar symptoms. He was isolated in the same manner, and the crew's effects were again treated in the disinfector. On arrival at Gravesend the ship was boarded by the assistant port medical officer, who ordered the removal of the patient and his attendants to the port hospital at Denton. Although no signs of disease among the ship's rats, of which there is a goodly number, were to be discovered, the company's rat catcher was ordered to cremate in the ship's furnaces the bodies of all the vermin he could catch.

Another Non-Combatant.—During the recent campaign on the Indian frontier, one of the line officers, Lieutenant Ford, was dangerously wounded in the shoulder and was bleeding to death from the bullet having cut the main artery, when Surgeon-Lieutenant Hugo came to his aid. The fire was too hot to permit lights to be used to examine the wound, and there was no cover; nevertheless, the surgeon struck a match and examined the wound. The match went out amid a splutter of bullets, which kicked up the dust all round, but by its uncertain light he saw the nature of the injury, and seized the bleeding artery, and, as no ligature was available, he remained for three hours under fire holding the vessel between his finger and thumb. When at length it seemed that the enemy had broken into camp, he picked up the officer, who was unconscious from loss of blood, and bore him into a place of safety without relaxing his hold of the artery. For this magnificent act of heroism the surgeon received the decoration of the Distinguished Service Order, which the *British Medical Journal* says "in these days is showered about after a campaign almost as liberally as a mention in dispatches." After reciting the story, our contemporary is moved to add: "Now, we say it with all deliberation, none of the many deeds of valor done by our soldiers in the Indian campaign equals that of this young medical officer, either in courage or in devotion to duty. Fighting men have the fierce joy of combat, and the excitement engendered by 'the pride, pomp, and circumstance of glorious war,' to stimulate and support them. Non-combatants have none of these adventitious aids to heroism. They must be obscurely brave without the cheers of comrades, and they must be content to fall without glory. Theirs is the very highest and truest courage, and it is deplorable that military etiquette or official pedantry should be allowed to stand in the way of its being properly rewarded. If ever any one deserved the Victoria Cross it is the man who did the splendid deed above recorded."

Obituary Notes.—Dr. William Carter Otterson, of Brooklyn, died of heart disease at Long Branch on August 17th, after an illness dating back to last summer. He was born in this city in 1829, and was graduated from the College of Physicians and Surgeons in 1853. In 1861 he was appointed brigade surgeon of volunteers, and he was assigned to the army of the Southwest as medical director. In the same capacity he was with the ninth corps at Vicksburg and with the twentieth corps on the march to the sea. Later in the civil war he had charge of a military hospital at Nashville, Tenn. He embodied his experiences of this time in a book entitled "Notes on Military Surgery during the Civil War." At the close of the civil war he resumed practice in Brooklyn. He was for two years sanitary inspector of the Brooklyn board of health, and at the same time chairman of the Brooklyn ambulance service, which was then in its first year. Later he was appointed deputy commissioner of the Brooklyn board of health. He was a member of a number of medical and social organizations. Because of failing health he had done but little practice during the past four or five years. He was a widower and three children survive him.—Dr. John Frederick Morse, of San Francisco, died at his home in that city on August 22d. Apoplexy was the cause of death. He was a graduate of the Medical College of the Pacific in 1878, and of the University of Berlin in 1881. He was a member of the California State board of health and of the San Francisco board of health, and enjoyed a wide reputation as a skilful surgeon.—Dr. Gardner Q. Colton died recently in Rotterdam. He was born in Vermont in 1814, and studied medicine at the College of Physicians and Surgeons in this city. He went to California in 1849 and worked in the gold fields, at the same time practising medicine among the miners. After leaving California he travelled through the United States, lecturing on nitrous-oxide gas, which he called "laughing-gas." In 1863 he established the Colton Dental Association in New York, using nitrous-oxide gas as an anæsthetic, following a suggestion which he said was made to him by Dr. Horace Wells in Hartford in 1844.

The Education of Deaf-Mutes in India.—There exist in the Indian empire, according to the most recent census, some one hundred and fifty thousand deaf-mutes. No provision has hitherto been made for the special education of the class, with the exception of a school in Bombay, containing about thirty pupils, and some private efforts of a limited description. The *British Medical Journal* states that a petition has recently been submitted to the secretary of state for India by some educated deaf-mutes of Bombay, pointing out the absence of organized and adequate arrangements such as exist in all civilized countries for the purpose of enabling persons afflicted with the loss of the sense of hearing and speech to overcome, in so far as that is possible, the serious disability thereby entailed, so as to fit them to participate in the enjoyment and utilization of life. The petition has been referred for the consideration of the government of India, and it is certain that the charitable impulses of Indian administrations which have inspired such magnificent undertakings for the relief and restoration of those disabled by sickness will result in the establishment of schools in all the principal centres of population for the special education of the deaf-mute.

The Use of Preservatives in Milk.—The chemists of the New Jersey State dairy commission have been making extensive analyses of milk and have found that a large number of samples contained boric acid or salicylic acid added as a preservative. The addition of these substances is a technical violation of the law against the adulteration of food. The matter has been brought to the attention of the State board of health, and it is thought that the board will make a ruling declaring the addition of these preservatives to be an adulteration, such as is forbidden by law. A ruling will also be asked for with reference to the putting of salicylic acid in catsup and other condiments. In a recent case of this sort the dairy commissioner prosecuted for food adulteration, but the jury acquitted the accused on the strength of expert testimony that the preservative used was not injurious to health.

The Investigations into the Causes of Camp Typhoid.—The board of medical officers, consisting of Surgeon-Majors Read, Vaughan, and Shakespeare, appointed to investigate the typhoid fever in the army camps, began its labors at Camp Alger on Saturday last. After concluding the investigation there, the board will proceed to the other points which have been designated in the official instructions. These are Camp Alger, Virginia; Camp Thomas, at Chickamauga; Camp Meade, at Middletown, Pa.; Camp Wikoff, at Montauk Point, N. Y.; and the camps at Huntsville, Ala.; Jacksonville, Fla.; and Fernandina, Fla.

The German Association of Naturalists and Physicians will meet this year at Düsseldorf from September 19th to 24th. The following addresses will be delivered in the general sessions: "A Century of Surgery," by Professor Tillmann, of Leipzig; "Causes and Beginnings of Disease," by Professor Martin, of Rostock; "The Importance of Nursing for Scientific Treatment," by Dr. Martin Mendelsohn, of Berlin. It is hoped that Professor Virchow will also deliver an address.

The Medical and Surgical Reports of the War.—The army surgeons in the field and camps are sending in complete reports of the cases which have come under their care, both medical and surgical. Although the war was brief, the number of sick and wounded soldiers thus far has been over forty-five thousand. The hospital records of this war will, it is claimed, be most complete, and will be eminently satisfactory from the statistician's point of view.

The American Association for the Advancement of Science was in session this week in Boston. The attendance was greater than had been anticipated, and many interesting papers on a great variety of subjects were read and discussed.

An Outrageous Assault on a Physician's Character.—According to the *British Medical Journal*, a Dr. Sheridan, of Stradone, Ireland, was recently placed in a most unpleasant position. He was called to see a young woman, and proceeded to make a vaginal examination. While so engaged, the mother of the girl shut and locked the door of the room, so that the doctor could not get out, and he had to call to his servant out of the window to go for the police. On their arrival, Dr. Sheridan was given into custody on the charge of rape. When he was brought to trial, the magistrates, after an investigation of the case, refused to entertain the charges, and the chairman stated that all the magistrates agreed with him in saying Dr. Sheridan left the court without a stain upon his character. The two fife and drum bands of the town turned out to welcome the doctor on his return home.

The Female Members of the British Medical Association.—On Thursday, July 28th, the medical women attending the meeting of the British Medical Association in Edinburgh held a special dinner, at which forty-two practitioners, all but three of them members of the association, were present. The only non-medical woman present was Miss Louisa Stevenson, a patient and successful worker in the cause of medical education for women in Great Britain. Dr. Sophia Jex-Blake was requested to take the chair. After dinner Dr. Jex-Blake proposed three toasts, which were received with acclamation: (1) "The Secretaries," who had proposed and carried out the arrangements for the dinner so successfully at twenty-four hours' notice. To this Dr. Jane Walker responded. (2) "The Guest of the Evening," to which Miss Stevenson responded. She said that it was in the struggle in Edinburgh nearly thirty years ago that the battle of medical education for women in the United Kingdom was really fought and won, and that but for that struggle no such assemblage as the present would have been possible. (3) "The Health of Dr. Garrett Anderson," the first woman who had obtained a British diploma, to whom all present owed a debt of gratitude. Dr. Garrett Anderson remarked that all was not yet won, and that she hoped to see medical women on a more absolute equality with medical men than was yet the case. Dr. Florence Boyd then proposed "The Health of Dr. Jex-Blake," and a vote of thanks for her acceptance of the chair. In responding to the toast, Dr. Jex-Blake begged her hearers to remember that, if the elder women had laid the foundation stones, the succeeding generation must build the walls and complete the edifice.

Worse than an Army Transport.—The *Berliner Post* says that during a recent passage up the Obi river of the Siberian convict ship *Angara*, going from Tiumen to Tomsk, in western Siberia, thirty-one out of five hundred prisoners died from suffocation and overcrowding.

The Johns Hopkins University, according to the *Medical Press and Circular*, is located in Washington. Our esteemed contemporary has an infallible instinct for the incorrect in its comments on America and Americans.

A Protest of Polish Physicians.—The following protest against the arbitrary action of the Prussian authorities in preventing a medical congress at Posen has been presented to the Austrian Parliament: "In the first days of August, 1898, the Polish Association for the Promotion of Medical and Natural Knowledge was expected to hold a meeting in Posen. Early in July the chief of the Posen police informed the organizing committee of the meeting that strangers (*i.e.*, Poles who were not Prussian subjects), would not be allowed to participate at the proceedings. The police authorities added, in the most brutal tone, that if any such persons came to Posen at the time of the meeting they would be immediately, and in the usual compulsory manner, expelled from the country. This measure is directed against a number of men, desirous of entertaining calm and friendly scientific intercourse. It is not too much to say that it violates the legitimate claims of science, with which the meeting was solely and uniquely to be concerned. For thirty years past the meetings of the Polish Association of Physicians and Naturalists have been held without difficulty or conflict. In the year 1884 a very successful gathering took place at Posen and no offence whatever was found to be the result. The motives of this prohibition are well known. In certain German circles it has become quite usual to incite against the Polish nationality, and to envenom the relations between this and the German nationality, the aim being to frustrate every intellectual enterprise, every undertaking of culture and civilization, if coming from Polish quarters. We feel bound to protest most emphatically against the measure adopted by the Prussian authorities at Posen." The memoir is signed by nearly sixty physicians and professors in the universities of Cracow and of Lemberg.

The Late Dr. John Blair Gibbs.—At a special meeting of the Society of Alumni of Bellevue Hospital, held July 13, 1898, to take action upon the death of John Blair Gibbs, M.D., assistant surgeon, U.S.N., who was killed at Guantanamo, Cuba, June 12, 1898, the following was presented and adopted:

"We are here assembled to mourn the loss of a comrade who had endeared himself to us all by his manly virtues, by his high attainments, by his patriotism, and by qualities which distinguish the gentleman and scholar.

"Our beloved associate, John Blair Gibbs, now rests in a land so distant that no mother's tears can be shed upon his brow, no flower cast upon his grave. But many sighs tell of the depth of affection for him who sacrificed his life in ministering to his disabled fellow-soldiers.

"While we deplore the untimely demise of one of the first heroes to perish in this war, we have the assurance that his death is honorable to his calling, glorious to his memory, and consoling to his family, to whom we resolve to send this note as an expression of our sincere condolence.

"*Resolved*, that the above be spread upon the society's minutes, and that a copy be forwarded to the medical journals."

LOUIS A. DI ZEREGA, M.D., *Secretary*.

The Passing of the German Scientist.—It is astonishing to the American that German medical men of world-wide reputation as investigators can throw stones at the American character with their right hands, while putting their left hands behind their backs to receive the unjustified profits from the American patents on their discoveries, and yet maintain a reputation for honor. It is a pleasure to reflect that no American physician of any reputation has ever so debased himself, and further that American medical ethics, with all its admitted shortcomings, has never yet descended to the German plane. How long in America would Behring be a leader of medicine after he had publicly patented, for the benefit of his own pocket, the results of the labors of Pasteur, Roux, Fraenkel, Kitasato, Aronson, Tizzoni, Ehrlich, and many others? Not very long certainly.—*Cleveland Journal of Medicine.*

We, in this country, are accustomed to be stigmatized as a people whose thoughts seldom, if ever, rise above the almighty dollar. We are contemptuously classed by the inhabitants of Europe with the English as a nation of shopkeepers, and the Germans have been most ready to cast this reproach in our teeth. But it can be safely asserted that in the Germany of the present day, to a greater extent than in any other civilized land, are its scientific men—with a few notable exceptions—saturated with the love of lucre.—*Pediatrics.*

The Hospital Ship "Relief" returned from Ponce, Porto Rico, on August 19th, having on board two hundred and forty-eight sick and wounded soldiers, of whom one hundred and fifty-four were suffering from typhoid fever. There were fourteen deaths, among them that of Major Lawrence S. Smith, surgeon of the first Pennsylvania volunteers. The typhoid fever, which is prevailing to a very serious extent among the troops in Porto Rico, was brought from the infected camps in this country.

Faith without Works.—A girl thirteen years old, whose parents live in Greenport, L. I., died recently of typhoid fever. The child's mother had refused to call in a physician until she was forced to do so by the local health officers. She was a faith curist and insisted that she could and would cure her child by prayer.

The Scandals in the Treatment of the Wounded and Enfeebled Soldiers at Montauk Point grow worse day by day, and the righteous indignation of the public becomes constantly more intense. The usually well-informed Washington correspondent of the Boston *Herald* reports that Secretary Alger continues to dismiss all criticism of the conduct of the war department as beneath notice, and says that he "proposes to order no courts of inquiry, much less to order any court-martials to settle responsibility and adjudge penalty for the deficiencies of the medical, commissary, and quartermaster's departments." On the same authority we are told that "President McKinley is apparently unwilling to make a breach with his secretary of war by insisting upon any impartial investigation."—*Evening Post.*

The Injury to the Prince of Wales.—*The Lancet* says that the present condition of the Prince of Wales' broken patella argues well for the future mobility of his joint, and thinks that he will not be permanently lame. "It will be a month before the Prince will be able to walk. Then his knee will be fitted with a check splint, by which flexion will be exactly controlled, and a spring apparatus will perform the function of the extensor. With the leg thus equipped, short excursions will be made on crutches, but it will be many weeks before his Royal Highness will walk unaided."

Sickness among the Troops at Porto Rico.—Illness among the American troops is on the increase, and there are now nearly a thousand cases of malaria and dysentery, with a few of typhoid fever. The army medical authorities have urgently recommended that the sick be sent North as rapidly as possible.

Dr. Antonio Jurada, recently surgeon on the *Vizcaya*, was released from custody a few days ago and sailed for Spain on Saturday last. He was advanced in years and suffered severely from exposure after the sinking of his ship. Upon arrival at Annapolis with the other Spanish prisoners he was found to be suffering from tuberculosis, and the disease made such rapid progress that it was feared he would be unable to reach Spain alive if his departure was delayed. Accordingly, the navy department directed his release, together with that of one of the chaplains, who was detailed to accompany the sick surgeon.

Foreign Titles in Great Britain.—A bill has been introduced into the house of commons making it compulsory for every person who attaches to his name the degree of bachelor, master, or doctor in any faculty in which degrees are granted (unless such degree has been received from a British university or other body in the United Kingdom entitled to confer degrees) to indicate clearly the source from which such degree has been received, under a penalty of forty shillings and costs.

A Woman Professor of Gynæcology.—The Dutch are far more liberal and up to date than their German neighbors, as witness the recent appointment of Dr. Katharina van Tusshenbroek to the chair of gynæcology in the University of Utrecht.

A French Anatomical Society.—Plans are being made for the foundation of a French "Association des Anatomistes," to include those interested not only in human and comparative anatomy, but also students of histology, embryology and anthropology. The association will meet annually in some university centre, Paris having been chosen for the place of the first meeting, to be held next year.—*Science.*

A Fool and his Cycle.—"Put a fool on a cycle and he will ride to destruction," makes a very good reading of an old saw, says *The Lancet*, and describes a situation which we can regard with equanimity. But when the fool on his way to his proper destination thinks well to smash into other people it is time to put a limit to his folly.

Reviews and Notices.

Atlas and Abstract of the Diseases of the Larynx. By Dr. L. Grünwald, of Munich. Authorized Translation from the German, Edited by Charles P. Grayson, M.D., Lecturer on Laryngology and Rhinology in the University of Pennsylvania; Physician-in-Charge, Throat and Nose Department, Hospital of the University of Pennsylvania. With 107 Colored Figures on 44 Plates, and 25 Text-Illustrations. Philadelphia: W. B. Saunders. 1898.

This is a good work of reference, being both practical and concise. The main features are the colored plates of pathological conditions, which are well executed and faithful, and illustrate the individual histories accompanying them. The microscopical plates add a value to the work. The type is large and the book is easily readable, and is a valuable addition to the existing laryngeal text-books.

Cardiac Failure and its Treatment. With Especial Reference to the Use of Baths and Exercise. By Alexander Morison, M.D. Ed., F.R.C.P. Ed., Physician to Out-Patients in the Great Northern and Central Hospitals, and in the Paddington Green Children's Hospital, etc. London: The Rebman Publishing Company, Ltd. 1897.

There are four parts and an appendix. The first has sections on percussion of the heart, landmarks, auscultation, extra cardiac signs, and signs in nervous diseases. The second part treats of the neuro-muscular and of the hæmic factors; the third part of general treatment; and the fourth part of treatment by baths and exercises. In an attempt to give full justice to those who have of recent years brought forth the modern method of treatment by baths and various forms of exercise, the author does not forget to mention those of the past whose contributions have materially added to our means of treating cardiac affections at the present day. In the preparation of this work there have been taken into consideration the character and general treatment of the conditions for which the baths and exercises are particularly adapted or advised. The subjects under discussion have received straightforward and serious consideration. There are many illustrations of heart or pulse curves; a few of pathological conditions, and a series of views showing the application of passive gymnastics or exercises against resistance. Dr. Grödel's appendix amplifies much that has been said showing the advantages of a Nauheim course for the cardiac patient. The fact that the author's experience has been gained outside of the bath resort, as well as at it, will make his conclusions the more unbiassed and convincing to many readers.

Fiftieth Anniversary of the Hartford Medical Society, Founded September 15, 1846. Proceedings at the Celebration, October 26, 1896, at Hartford, Conn.

An historical address, memoirs of departed members, remarks by the president, and the very clever postprandial exercises make up this little book. The attractiveness of the binding is enhanced by the Red Cross cover.

Proceedings of the Dedication of the Hunt Memorial Building by the Hartford Medical Society, February 1, 1898.

The "Proceedings" are of interest as illustrating the eagerness with which a medical fraternity grasps any proffered assistance tending to the advancement of medical science. The Hartford Society deserves credit for the enthusiasm displayed in the fulfilment of the terms of the bequest.

Hay Fever and its Successful Treatment. By W. C. Hallopeter, A.M., M.D., Clinical Professor of Pædiatrics in the Medico-Chirurgical College of Philadelphia, Physician to the Methodist Episcopal Hospital, etc. Philadelphia: P. Blakiston, Son & Co. 1898.

In this little volume of one hundred and twelve pages, exclusive of a bibliography going back to 1565, we are given the author's method, by which he has relieved completely over two hundred patients from this troublesome affection. After the general remarks and a history, the exciting causes are enumerated, and then follow symptoms, pathology, and treatment. The careful and thorough antiseptic rules laid down are worthy of attention.

State Board of Health. Seventeenth Annual Report. Albany and New York: State Printers. 1898.

This comprises two handsomely bound volumes, the second containing maps of the sewerage systems in various towns and cities. The wide range of information is of value to all interested in sanitation and health-board work.

The Retrospect of Medicine. A Half-Yearly Journal. Edited by James Braithwaite, M.D., and E. F. Trevelyan, M.D. Lond., B.Sc., M.R.C.P. Vol. CXVII., July, 1898. London: Simpson, Marshall, Hamilton, Kent & Co., Ltd.

The usual attractiveness of this publication is maintained in the present issue. After the alphabetically arranged synopsis follow selections from the year's literature on medicine, surgery, obstetrics, etc. The choice of material is, for the most part, good, and American writings are well represented.

A System of Practical Medicine. By American Authors. Edited by Alfred Lee Loomis, M.D., late Professor of Pathology and Practical Medicine in the New York University, and William Gilman Thompson, M.D., Professor of Medicine in the Cornell University Medical College, New York. In Four Imperial Octavo Volumes. Volume IV.—Diseases of the Nervous System and Mind; Vasomotor and Trophic Disorders; Diseases of the Muscles; Osteomalacia; Rachitis; Rheumatism; Arthritis; Gout; Lithæmia; Obesity; Scurvy; Addison's Disease. 1,099 pages, 95 engravings, and 8 full-page plates in colors and monochrome. Philadelphia and New York: Lea Brothers & Co. 1898.

This, the last volume of the "System," is devoted mainly to diseases of the nerves and mental affections. There is, however, a chapter on diseases of the muscles, and some ten miscellaneous subjects have received attention at the hands of Dr. W. G. Thompson himself. In the list of contributors are such well-known names as Dana, Starr, Dercum, Coleman, Eskridge, Finley, Fisher, Gray, Herter, Bailey, Jacobi, Peterson, Putnam, Noyes, Mills, and many others. A vast amount of work has been put into this "System," and the present volume reflects credit upon every author who has helped bring the undertaking to a successful issue. The surviving editor is to be congratulated upon completing the work left to his efforts alone by the unfortunate and untimely death of his associate. Not only have the editorial duties and difficulties been successfully accomplished, but the editor has found time to contribute many important chapters. The publishers' part has been well done. The volume index is full, and there is a general index to all four volumes.

Archives of the Roentgen Ray. Edited by W. W. S. Hedley, M.D., and Sydney Rowland, M.A. London: The Rebman Publishing Company, Ltd.

We have had occasion several times to call attention to this interesting and progressive periodical, formerly *The Archives of Skiagraphy*. The issue now before us has the usual number of illustrations and interesting articles.

Diseases of the Skin. Their Constitutional Nature and Cure. By J. Compton Burnett, M.D., Author of "Ringworm: Its Constitutional Nature and Cure." Third Edition, Revised and Enlarged. Philadelphia: Boericke & Tafel. 1898.

The title of this book is misleading. The two hundred and fifty diminutive pages, taken up chiefly with the relation of personal cases more or *less* convincing, can in no sense be taken as a serious treatise on modern dermatology. The author has a hobby that almost all ills arise from eruptions "driven in" by usual methods of treatment, and that by reproduction of a skin eruption the constitutional affection can be made to disappear again. This hobby is ridden with so much *post hoc* spurring and such an amount of *propter hoc* whipping that one is led to the conclusion that either previous editions must have been small ones, or that many of those who made the present edition a possibility were actuated by sentiments of curiosity. Grains of truth are scattered through the pages, but the work should never have been allowed to go

out as a guide to students of homœopathy as to what scientific dermatology really implies. To those capable of appreciating those things which the author lacks or hides it will prove an interesting and at times instructive book.

TEXT-BOOK OF DISEASES OF THE KIDNEYS AND GENITO-URINARY ORGANS. By PROF. DR. PAUL FÜRBRINGER, Director of the Friedrichshain Hospital, Berlin; Royal Medical Councillor and Member of the Royal Medical Council of the Province of Brandenburg, etc. Translated from the German with Annotations by W. H. GILBERT, M.D., Physician in Baden-Baden; Physician to the Sanatorium of Dr. Frey-Gilbert, Baden-Baden, etc. In Two Volumes. Volume II. London: H. K. Lewis. 1898.

THE second volume of this excellent work, which has been well translated, opens with a consideration of pyelitis and pyelonephritis. Following chapters on tumors and abnormalities, diseases of the biadder are considered, and then those of the urethra. After the diseases of the genital organs come a bibliography and then the index. The bibliography is quite full, covering twenty-three pages. Urinary sediments furnish about the only illustrations. The chapters are almost without exception written in an entertaining style and indicate a master mind.

Clinical Department.

AN EPILEPTIC FIT LASTING FORTY-FIVE MINUTES.

BY L. PIERCE CLARK, M.D.,

FIRST ASSISTANT PHYSICIAN, CRAIG COLONY FOR EPILEPTICS, SONYEA, N. Y.

IT is well known by those accustomed to seeing many cases of epilepsy that the fits frequently occur in series in such a relationship to one another that one attack may appear to run into or overlap the other. Again, an epileptic paroxysm may be so incomplete in the character of its discharge that a slight irregular muscular convulsion will persist at varying periods for hours or even days afterward. In the first instance spoken of, that of attacks occurring in series, the patient remains in a condition of coma, from which he arouses sufficiently to pass through his serial fits. This last-named state is commonly termed status epilepticus.

Single isolated attacks of epilepsy rarely last more than three minutes. Cases have been placed on record of ten and possibly fifteen minutes, and the patient has not materially suffered from the effects.

Apropos to the foregoing remarks, I wish to place on record a very unusual case of epilepsy, in which the convulsive movements of the epileptic fit lasted for forty-five minutes.

J. S. McA——, male, aged thirteen years. His epilepsy began when he was six months of age, at the time of dentition. The patient is the fifth child in a family of five. A paternal aunt died of phthisis. His father had curvature of the spine and died of spinal meningitis: he was also somewhat demented before his death. A paternal uncle was insane. Two of the patient's brothers had convulsions at dentition. During infancy the patient had several attacks of summer complaint, and these were always attended by convulsions. The patient's mother had three sisters who suffered from sick headaches and "neuralgic attacks." In early infancy the patient frequently suffered from night terrors and disordered sleep. The attacks at first most frequently involved the left side. The early onset of the patient's epilepsy has materially interfered with his mental development.

March 19, 1898, I was called to see the patient, who was in a continuous clonic spasm. The muscular convulsion was most marked in the left arm and right leg, although all skeletal muscles were involved in the convulsion. The patient had been in a continuous spasm for twenty minutes prior to my seeing him. This condition continued, although the ordinary means were used to stop the seizure. At the end of about forty minutes of continuous clonic movements, the patient's temperature registered 103° F., although he had begun in a condition of ordinary health. At the end of the forty minutes inhalations of chloroform were given. About five minutes after this, at the completion of the forty-five-minute period, the convulsions had almost entirely ceased and very soon ceased altogether. The patient passed into a condition of coma. The pulse rate was 146, and the temperature remained high. Extreme and profuse perspiration had resulted. The patient remained in a comatose condition, unable to be aroused, for thirty-six hours thereafter, the temperature gradually returning to normal. It reached its normal limit at the end of forty-eight hours. The patient was somewhat confused for two or three days.

At no time did this attack give the appearance of being what is frequently termed by French writers "subintrant or imbricated attacks." The spasm was regular and rhythmical at all times, and it was evidently one continuous seizure throughout. Apparently this attack was primarily caused by stomachic indigestion; the patient has had frequent attacks in which an initiative vomiting was the prominent feature of the paroxysm.

HERNIA OF THE BLADDER.

BY T. E. SCHUMPERT, M.D.,

SURGEON TO THE CHARITY HOSPITAL, SHREVEPORT, LA.

JOHN C——, aged forty-six, Italian, groceryman; weight, two hundred and twenty-eight pounds; came to my office, March 2d, to consult me with regard to what he designated a left oblique inguinal hernia. After an examination, I verified his diagnosis and advised an operation for the radical cure, explaining to him the impracticability of a truss in his case, owing to the shape of his abdomen and the thickness of the abdominal wall. The operation was consented to at once, and it could readily be seen that he had decided already that this was the only thing to be done, as he stated that he had tried trusses without any relief. He further stated that he wished the operation immediately, and would not be put off until the next morning. So 4 P.M. was the hour set, and, after all usual preliminaries, I proceeded to operate. My first incision revealed a very thick abdominal wall with a large hernial mass of postperitoneal fat. The empty sac was soon found and freed of its posterior and lateral adhesions and disposed of in the usual manner. What yet remained of the hernia was too large to incorporate in one or two ligatures. So I began at the top and split down and ligated away, section by section, until three ligatures were employed. Then as I proceeded in the same manner with the last remaining segment, with one snip of my scissors a copious flow of amber-colored fluid escaped. This I recognized at once to be urine and as soon realized the gravity of my mistake. The bladder, which was entirely hidden, was now dissected clear and placed in the upper angle of my parietal incision, with the cord alongside of it. The ring was then closed with kangaroo tendon and the skin wound closed with continuous catgut, including the incision in the bladder, which was sutured to the skin incision, thus forming a urinary fistula. My patient rallied nicely, and the urine continued to flow through the wound copiously, necessitating a change of dressing three or four times a day. His temperature never rose beyond 100° F., and the abdominal wound healed primarily.

On the tenth day under cocaine anæsthesia I dissected out the fistulous tract entirely and closed the

abdomen with deep catgut sutures, and the skin wound with the same, save where a small drainage tube was inserted. This wound also healed kindly, and in two weeks more my patient was discharged cured.

I report this case because such conditions are rare and little has been written on the subject during the last few years. Had it been more written about, the anticipation would have been fresher in my mind, and possibly, though not probably (in this case), I should have avoided this sore mistake. I perceived no glistening surface to warn me, nay, apparently nothing but a large mass of fat. Who would have suspected that a viscus would be disclosed so foreign to its domain? Hernia of the bladder must necessarily be rare, owing to its anatomical disposition. Such men as Cooper, Scarpa, Percival, Pott, and others have witnessed it not more than once or twice, and John A. Wyeth says: "I have witnessed two cases in which the bladder was wounded in an operation for supposed intestinal hernia of the oblique inguinal variety." Pott records a case in which he cut into a cystic hernia, on the supposition that he was dealing with a dislocated testicle; and there are other instances in which the trouble has been mistaken for hydrocele, abscess, or inflammatory enlargement about the groins. Marcy records a case that had been diagnosed hernia of the testicle on two previous occasions. While he was not inclined to agree in the diagnosis, he was yet in doubt. He says: "I made my incision through the skin and cellular membrane, by means of which I discovered a firm, white, membranous cyst connected loosely with the cellular membrane in the same manner as a hernial sac. I dissected this bag quite clean, and found, as I traced it upward, it became narrow and seemed to proceed from the upper part of the groin. I cut it off at the constricted portion. Upon the division there issued forth about four ounces of urine." Thus it may be seen how rare these complications are, and difficult for even the most experienced to deal with.

HYDRONEPHROSIS CAUSED BY ENLARGED PROLAPSED LEUKÆMIC SPLEEN.

By CHARLES C. ALLISON, M.D.,

OMAHA, NEB.

On October 14, 1897, I examined Mrs. C——, married, aged forty-two years; family history negative. The patient has borne eight children, and until early in 1894 her health had been good. Prior to this time the patient's home was in London, but in 1894 she moved to Chicago, where she was treated for malarial fever; and with this illness dates the appearance of an enlargement on the left side of the abdomen. The abdominal distention continued to increase, becoming more general, and attained the size of full-term pregnancy. At this time well-marked anuria was noted, with impaired digestion and persistent hæmatemesis. Coincident with a sudden polyuria, which commenced in the night and recurred on the three or four succeeding nights, the abdomen rapidly diminished in size. The urine was described as thick, brownish in color, and very abundant; the quantity passed on each night is said to have been over a gallon. These phenomena have been repeated three times since 1894, marked improvement in the patient's comfort and subsidence of the abdominal enlargement having followed the free discharge of highly colored urine.

Examination reveals a large movable mass over the left upper and half of the left lower quadrants of the abdomen. The border of the tumor is sharply defined, and describes a broad curve from the left costal arch to the iliac crest. Dulness extends over the entire area and as high as the tenth rib. The location, the size, and the shape of the enlargement point plainly to enlarged spleen. Blood examination is as follows: Hæmoglobin, seventy-five per cent. Corpuscles (mean of five counts)—red, 3,680,000; white, 9,000. Leucocytes—small mononuclear, large mononuclear, and polynuclear, decrease; transitional, marked increase; eosinophiles, very marked increase.

Few nucleated red blood corpuscles were found, and no bone-marrow corpuscles. Fifty per cent. of the leucocytes in the differential count consisted of eosinophiles. This, while not characteristic of a leukæmic enlargement of the spleen, yet pointed to that condition, and the clear history of a hydronephrosis which developed after the enlargement of the left side was first noted would make it strongly presumptive that the enlarged spleen caused an obstruction by pressing upon the ureter, and led to this additional abdominal enlargement.

Operative treatment for enlargement of the spleen due to leukæmia has never been in favor. The most complete report is made by Dr. Richard Douglas (*Journal of the American Medical Association*, April, 1896), in which 149 splenectomies are recorded: 36 operations for leucocythæmia, with 31 deaths; 59 operations for hypertrophy, with 25 deaths; 5 operations for neoplasms, with 3 deaths; 6 operations for hydatid disease, with 2 deaths; 43 operations for wounds, with 11 deaths. A recent report by Jonnesco (*Annals of Surgery*, 1897) includes 11 splenectomies for malarial disease and 1 for hydatids with no deaths.

In view of the figures given by Douglas, and more especially bearing in mind that the other reports of operating for leukæmic enlargement of the spleen are even less favorable, it is plainly conservative to depend upon other measures for the relief of this condition.

A CASE OF HODGKIN'S DISEASE.

By J. J. MORRISSEY, A.M., M.D.,

VISITING PHYSICIAN TO ST. JOSEPH'S HOSPITAL, NEW YORK.

Through the kindness of Dr. C. M. Cauldwell, chief of the staff of St. Joseph's Hospital, the writer is enabled to report the following case, which was lately in our wards at St. Joseph's Hospital. Pseudo-leukæmia is commonly called Hodgkin's disease, from the well-known morbid anatomist of Guy's Hospital, who first described in detail its general features. Before his time the disease had no definite recognition and its pathological characteristics were not understood; but his careful researches, supplemented by those of Virchow and Cohnheim, have given it a place and an importance worthy of its destinctive character. In the majority of cases there is to be found an antecedent history of syphilis, malarial poisoning, or, combined with these, a local irritation, from which the disease rapidly spreads. In the case cited, however, the history was absolutely negative. There appears to be no recognizable cause preceding the development of the glandular irritation, and the entire history of the patient would seem to preclude the possibility of an active, specific poison.

Mrs. C——, forty years of age, stout in body and of phlegmatic temperament, some four years ago had an attack of what was called by her attending physician muscular rheumatism. She was pregnant at the time, and some three months afterward the child was born. Shortly after this occurrence she noticed that two glands in the left cervical region were enlarged, but freely movable beneath the tissues. Slowly they increased, and her physician, evidently basing his diagnosis upon the fact that two of the patient's brothers had died of phthisis, concluded that tuberculous adenitis was present, and advised their removal. The cicatrices still mark the locality whence the glands

were removed. At a later period other glands on the right side of the neck became prominent and rapidly increased in size. At this time the general nutrition of the patient had not been interfered with, and she suffered but slight inconvenience in attending to her household duties. One of these glands was also subjected to surgical examination, but the operation appeared to intensify the development of the others, and she would not permit further interference.

From the patient's statement, a microscopical examination of the blood had not been made, and evidently a correct diagnosis had not been reached. She was advised to consult the late Dr. Cronyn, of Buffalo. He immediately detected the gravity of the disease, informed her as to its nature, and gave an unfavorable prognosis. He strongly deprecated further interference with the glands, unless the exigency of the case demanded their removal. Since that time a rapid interference with the functions of the glandular tissue in several portions of the body has taken place, and the diagnosis has been confirmed in every particular.

Status præsens: The glands of the neck are swollen and tender, and are increasing in size, those of the left side predominating. The glandular infiltration of the axillæ is especially prominent, but not so painful as in the cervical region. The inguinal glands appear to partake of the general involvement. For the past three months the patient has also noticed that there is a slowly developing enlargement of the left hypochondriac region, the dimensions of which cannot be accurately determined on account of the excessive amount of adipose tissue. The spleen is easily palpable, and on pressure somewhat painful, while over the liver percussion evokes decided tenderness. The latter organ does not appear to be increased beyond its normal anatomical relations. There are no marked pressure symptoms, nor is there interference with the circulation, either in the thorax, abdomen, or cranial cavity. The mind is clear and cerebral activity unimpaired. (It should have been mentioned that the cervical glands of the right side occupy the entire space between the inferior maxillary and the clavicle, and can be pressed upon without eliciting pain.) The voice is "thick," the tonsils are hypertrophied. There is no decided interference with deglutition. There is a slight deafness, probably due to the growth of the adenoid tissue in the pharynx close to the Eustachian tubes. The anæmia, which gradually manifested itself subsequent to the enlargement of the cervical glands, is not of a profound type and certainly cannot be said to be characteristic. However, there may exist enormous enlargement of the lymph glands without marked anæmia (Osler). It would appear that the younger the patient the more acute the manifestations, and, in consequence, the cachectic condition discloses itself at an earlier period.

In conjunction with the symptoms described above, there is breathlessness on the slightest exertion. A careful examination of the cardiac region failed to show anything abnormal, except a slight innocuous murmur, probably functional in character. The pulse is weak but not irregular, and, considering the protracted course of the disease, the heart may be said to be in fairly good condition, the beats averaging 112 to the minute. The fever is continuous, with slight diurnal variations, the thermometric curve seldom exceeding 101 F. There has been no epistaxis.

A microscopic examination of the blood failed to show any of the characteristics of a true leukæmia, as the blood corpuscles did not fall below 3,500,000 per cubic millimetre, and there was scarcely any poikilocytosis. A few nucleated red blood corpuscles were present. Lymphocytes were found in abundance.

Mrs. C—— has three living children, all of whom are apparently in the enjoyment of excellent health, and up to the inception of the disease she possessed remarkable vigor. Two brothers, as stated above, died of tuberculosis, while her other relatives, so far as she knows, are free from disease. There is no history of repeated miscarriages or of symptoms pointing to a specific taint. Menstruation persisted up to two months ago, and with such regularity that the patient now considers herself to be pregnant.

The treatment adopted since the disease was first recognized has been classic in character, arsenic in the form of Fowler's solution and phosphorus having been freely administered. The patient believes there was a marked decrease in the cervical swellings while her system was under the influence of the medicine. Too much reliance should not be placed upon this alleged improvement, for, as is well known, there may be marked fluctuations in the dimensions of the enlargements irrespective of the administration of remedies.

2052 Madison Avenue.

FILARIA OSLERI.

By ERNEST B. SANGREE, A.M., M.D.,

Professor of Pathology and Bacteriology in the Medical Department of Vanderbilt University, Nashville, Tenn.

Some weeks since, while my chief assistant, Dr. Louis Leroy, was looking over a section of dog's lung, one of several hundred that had been cut for the class in normal histology, he discovered the parasite figured in the accompanying illustration. At my suggestion he

examined all the rest of the sections, and succeeded in finding five more showing portions of the worm. As I was not certain as to the parasite's identity, I sent one specimen to Prof. Edwin Klebs with a query. He replied that he thought it was a species of strongylus, though he could not say positively without seeing the head. He also remarked that it was strange to find no inflammatory reaction in the neighborhood of the

worm. The head, by the way, we do not seem able to find.

Another section I sent to the bureau of animal industry at Washington, D. C., with a similar query, and Dr. D. V. Salmon, chief of the bureau, was kind enough to have the specimen examined and send me the following reply:

"U. S. Department of Agriculture,
"Bureau of Animal Industry,
"Washington, D. C., February 17, 1898.

"*Dr. Ernest B. Sangree, Nashville, Tenn.*

"Dear Doctor: The specimen mentioned in your letter of the 9th inst. has been duly received. I should not be willing to risk a positive opinion on the parasite without having an entire worm before me, but in all probability the worm is Filaria Osleri (Cobbold, 1879), originally mentioned by Osler in 1877 as Strongylus bronchialis canis. The specimen evidently represents a single worm, and the spiral twisted bodies are embryos. Very respectfully,

"D. E. Salmon, *Chief of Bureau.*"

Strongylus is rare in the human, but different varieties of this type of worm are not uncommon in animals, such as sheep, goats, rabbits, deer, dogs, cows, horses, and birds; and seem to have a special predilection for the lungs, where they occasion inflammation. But as in all probability not many physicians have run across one of these parasites in their microscopical work, I thought a note on it and an illustration might prove of interest.

SUDDEN DEATH AFTER CONFINEMENT.

By R. S. JOYCE, M.D.,
OGDEN, UTAH.

The patient was a multipara, mother of eight children, all large at birth. At her last confinement, two years ago, as the midwife reports, the patient had a "sinking-spell," became very cold, and was with difficulty kept alive. The facts in the present case are about as follows: Three weeks before her delivery the waters broke and had since come away freely. She had also had a discharge of meconium from the vagina for the past two weeks. When seen by me on the day of her death, she exhibited all the outward symptoms of a full-term pregnancy. The shoulder presented, and the presentation was converted into a vertex one with difficulty. Pains were at intervals of fifteen minutes, and very severe. After waiting two hours without any appreciable advancement, I put on high-traction forceps and brought the head low down on the perineum, and then removed the forceps. The woman then began to have her first real bearing-down pain, and child was soon expelled. When the forceps were removed the blades were covered with bright yellow fæcal matter, and this also covered the child at birth. The child was dead, and had no doubt been dead for some time, as the cord was friable and broke easily. The placenta was soon removed and no great loss of blood occurred. The child weighed eighteen pounds and looked like a child a year old. Within a few moments after the fœtus was delivered and before the placenta was discharged, the mother complained of being cold and of great difficulty in getting her breath. There was no post-partum hemorrhage. The dyspnœa increased rapidly, the face became white and anxious, and the lips blue. She rolled and tossed on the bed, despite all efforts to quiet her. She had full consciousness and felt the gravity of her condition, insisting that she was about to die. Morphine failed to give even temporary quiet, and large doses of brandy had no influence apparently on the circulation. She took the brandy ravenously. In an effort to raise her head, about two hours after delivery, she suddenly fell back dead. No autopsy was permitted, but her death was no doubt due to venous thrombosis.

A point of great interest in this case was the abundant discharge of meconium for two weeks before labor. The death of the fœtus in this case was no doubt due to asphyxia. The size of the fœtus, which I weighed accurately, and death from venous thrombosis, all together make a combination of accidents which are not often met. There was no recto-vaginal fistula.

A PATENT URACHUS.

By WALTON PRESTON, M.D.,
SAN FRANCISCO, CAL.

I would like to report a case anent the reference in a recent issue to cases of "Congenital Absence of the Penis." In 1876, while living in Benzonia, Mich., I was called to a case of complete absence of the sexual organs. The mother was delivered a few days before by a midwife, and I was sent for with the hope that "something" might be done to declare the sex of the infant. The child was otherwise well developed and weighed nine pounds; the parents were young and healthy, and with no previous history of any malformations so far as could be traced. Above and below the umbilicus, but in contact with each other, were two growths resembling very much in color and consistence the liver. On separation of the neoplasms, urine was seen to escape through the urachus. A compress was kept over the parts, and from the amount of saturation a normal amount of urine was apparently voided. Two years later I was again sent for to see the child, who was suffering from some slight ailment. At that time the child was very robust and masculine in its habits. The neoplasms were somewhat larger and the urine continued to escape through the urachus. The mother informed me that there was never any urinary odor on the diapers used to receive the fæces.

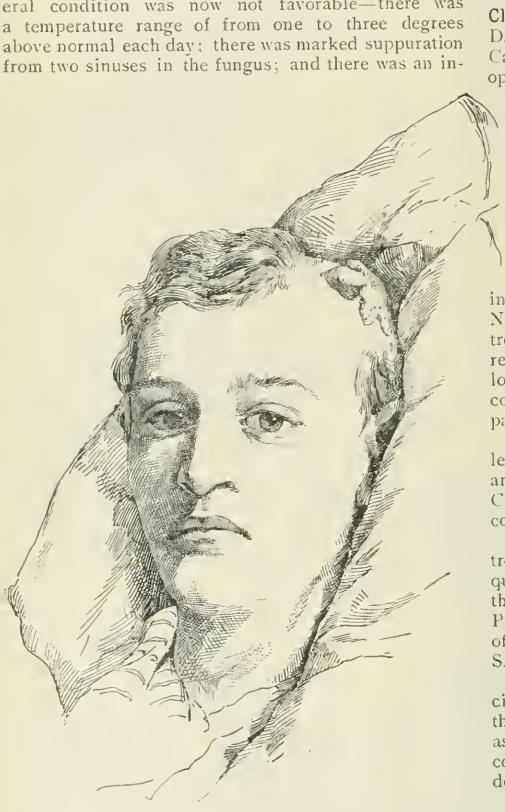
A CASE OF FUNGUS CEREBRI.

By T. S. McMULLAN, M.D.,
HERTFORD, N. C.

On December 21, 1897, I was hurriedly called to see a lad, fourteen years old, who had been shot accidentally with a pistol, 32 calibre, in the hands of one of his companions. The ball struck the cranium just over the third left frontal convolution, carrying away both tables of the skull for a space one and a half inches long by three-fourths of an inch wide, depressing the edges of the fracture and causing great comminution and impaction of the fragments. The ball had not penetrated the brain and was found embedded in the inner lamina; but the pieces of bone had badly lacerated the dura, were deeply embedded in the brain substance, and had caused great contusion of and some exudation of gray matter. The boy showed marked symptoms of compression, aphasia, and right facial paralysis.

It was not deemed necessary to trephine, the opening being of sufficient extent to allow what manipulation was needful; so, after elevating the depressed fragments, removing all the impacted pieces, and with a pair of fine forceps seizing and taking out the particles embedded in the brain substance, I washed out the wound with peroxide of hydrogen, inserted a piece of iodoform gauze, and left the wound (I mean, of course, the scalp incision, which was large) open. For ten days no untoward event took place. There were no increase in the aphasia, no fever, no suppuration, no

further symptoms of compression; and the wound seemed to be progressing toward a final cure. At the end of this time there appeared in its centre a small mass, of the color and feel of cartilage, which was attached by a pedicle to the underlying structures. This mass continued to increase in size, expanding upward and outward, until at the end of five weeks from the time of the shooting it had almost amalgamated with the tissues on each side, and, having lost its original color and feel, had the appearance of a mass of granulations. The accompanying illustration will show its size and appearance at this time. The patient's general condition was now not favorable—there was a temperature range of from one to three degrees above normal each day; there was marked suppuration from two sinuses in the fungus; and there was an in-



crease in the symptoms of compression, more marked aphasia, and more evident facial paralysis. His vitality was very low, and it required stimulation and a very condensed diet to tide over this crisis. During the whole time the most rigid antisepsis had been attempted—daily irrigations with hydrogen dioxide and daily (and often several times a day) dressings with iodoform gauze. The only method which I used to reduce this hernia was compression, systematic, the pressure being adjusted in accordance with the symptoms manifested. After the first week a decided diminution in the size of the tumor was noticeable, and at the expiration of the tenth week from the time of the accident there was no evidence of any abnormal growth; the sinuses had all kindly healed, the external wound had closed, the facial paralysis had disappeared, and the only relic of a very unfortunate and dangerous condition was a slight aphasia and a depression of the soft parts covering the aperture in the skull. The patient has been long since discharged, and there is now very little evidence of the original trouble.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-Sixth Annual Meeting, Held in Edinburgh, July 26, 27, 28, and 29, 1898.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 286.*)

SECTION OF MEDICINE.

Second Day—Thursday, July 28th.

Climate in the Treatment of Disease.—DR. THOMAS DAVIDSON, of California, read a paper upon Southern California, and DR. JOHN CALWELL advocated the open-air treatment of consumption, while DR. GUILLEMARD, of Cape Colony, related his experiences in the veldt of South Africa, which he recommended as a resort for consumptives.

DR. SYDNEY JONES, of New South Wales, said that while the seaboard of that colony was unsuitable for consumptives, the high internal plains and mountain slopes were of the greatest value in the climatic treatment of the disease. He referred to the many hardships suffered by young consumptives of small means, who were sometimes induced to leave this country in the hope of cure in New South Wales, and who landed there in an extremely bad state of health and without the pecuniary resources which would enable them to reach suitable localities. He was endeavoring, he said, to start farm colonies in New South Wales, to which such poor patients could be sent.

DR. JANE WALKER, of London, described the excellent results she had obtained by open-air treatment and high feeding on a farm in Norfolk; and DR. CHURCHILL, of London, showed plans of an ideal seacoast sanatorium on the chalk cliffs.

Vascular Tension.—SIR WILLIAM BROADBENT introduced a discussion on the significance and consequences of different states of vascular tension, with their general management, which was continued by PROFESSOR BRADBURY, of Cambridge; DR. SAVILL, of London; DR. HANDFORD, of Nottingham; DR. SAMMAYS, of Mentone; and others.

DR. DENTON JOHNS was of the opinion that physicians should lose no time in acquainting patients with the gravity of their condition when it really was grave, as they (the patients) would then be more likely to conform faithfully to the rules and regulations laid down for their treatment.

Third Day—Friday, July 29th.

Bacteriological Problems.—DR. WRIGHT, of the Army Medical School, Netley, gave a lengthy address on bacteriology and antitoxin, but spoke so fast and so indistinctly that it was very difficult and sometimes impossible to follow him. He was wholly in favor of orrhotherapy, for which he claimed a great future. Some of his conclusions, however, were subsequently traversed by other speakers.

DR. MITCHELL BRUCE, of London, gave an account of three cases of diphtheria which he treated with injections of antitoxin, with the happiest result in each.

DR. ALLISON asked if Professor Wright ever administered antitoxin by the mouth. He had done so himself, and found it a method preferable to subcutaneous injection.

In his reply, DR. WRIGHT appeared to intimate that some at least of his experiments were performed upon himself: he did not give antitoxin by the mouth, and thought that much of its beneficial effect was lost when it was used in that way. He mentioned that he had

found injections of diphtheritic serum an antidote for syphilitic ulcerations.

Hydrotherapy in Fever.—Dr. Jules Guiart, of Paris, spoke of the treatment of fevers by the cold bath, and said that bathing, in addition to reducing the temperature, acted as a diuretic, as much as seven quarts of water being sometimes passed under this influence in the twenty-four hours—a deluge that washed the toxic substances out of the system. In one case he mentioned that the patient had no less than one hundred and twenty cold baths before the desired effect was produced; it was almost a hopeless case to all appearance, the pulse being uncountable and the patient practically moribund, but she happily recovered. He then mentioned a case of measles which progressed favorably until the sixth day of the fever, when sickness set in; the child then became delirious, with a temperature of 106° F. and toxic dyspnœa. Not without difficulty he obtained permission to place her in a bath of the temperature of 18° C., and with good effect, for one hour afterward the temperature had fallen to 104° F. and the child perspired freely—one of the results he (Dr. Guiart) looked for from the use of the cold bath; and after the second bath this child was quite well.

In a case of scarlet fever the pulse was 150, only two ounces of urine was passed in twenty-four hours, and the patient was almost comatose when placed in the cold bath, in which she almost died, her skin turning blue, so that wine had to be administered and caffeine injected subcutaneously; but an improvement was soon manifest, though the patient had between twenty and thirty baths before she was out of danger. He considered that the bad symptoms in this case were due to the small quantity of water (two ounces) passed during the previous four and twenty hours; but in the first bath she urinated freely, for the water had a strong urinous smell when the patient was taken out of it, and, strange to say, no more urine was passed afterward until the patient was again placed in the bath. The cold evidently made her urinate. Eventually the patient made a good recovery.

Movable Kidney.—Dr. Cutwell exhibited a belt of his own devising for use in cases of floating or fallen kidney, which he said were of much more frequent occurrence than was generally supposed; his belt, he thought, would render operative interference unnecessary in such cases in future.

The Cinematograph in Medicine.—Dr. E. Doyen, of Paris, gave three most interesting cinematographic demonstrations. The first was of an operating-table of his own devising, adaptable for every case needing surgical aid; the second was of an operation for the removal of an abdominal tumor from a patient, which occupied about three minutes in the performance; and the third was of the preparation of a head for the removal, a week later, of a cerebral tumor. The scalp divided, a flap of skull was cut with a saw of Dr. Doyen's own device, a bony flap was raised, and the scalp was sutured again, the whole operation occupying about three minutes. Dr. Doyen's saw seemed to cut through the bone like a knife cutting butter rather than to divide it in the ordinary way. Altogether it was a most realistic and absorbingly interesting demonstration.

SECTION ON SURGERY.

First Day—Wednesday, July 27th.

The president, Dr. John Duncan, in his opening address, said that in Edinburgh they had been engaged in putting their medical house in order. The staple commodity of Edinburgh was education, medical and general. To one looking back, as he did, for thirty or forty years, nothing was more striking than the increasing importance of the examination system. Examinations were formerly intended merely to eliminate the unfit. Now they dominated the teaching. He hoped that they would soon succeed in so far educating the examiners that they would recognize that candidates were not finished practitioners, but that the chief business of the teacher was to make the student think and that the examiner's business was to find out how far the teacher had succeeded in each case. Increased attention was now given to practical and clinical work. The laboratories and museums attached to various departments of the university and to the Colleges of Physicians and Surgeons were evidences of this. In the Edinburgh Royal Infirmary arrangements were now all but completed for placing a surgical theatre at the disposal of each set of wards. The antiseptic system had so widened the field of surgery and population had so increased that the youngest assistant surgeon in the infirmary now performed as many operations as were done in the whole infirmary in the days of Syme.

Students did not flock nowadays to the surgical theatre as the populace used to flock to an execution. The glorification of mere manual dexterity had greatly diminished, and a surgical operation had come to be regarded as an incident in a case, and the theatre had become an appanage to the ward, in which whatever manipulation was necessary might be carried out in the way most advantageous to the patient, and most beneficial to the student as a sequel to the diagnosis and as a preliminary to the after-treatment.

Not only had the new theatres been constructed according to modern ideas, but the older had also been remodelled on the same lines. The managers deserved all credit for this endeavor to meet modern requirements, but the speaker did not have great faith in surgical upholstery. He did not believe that the expense which had been incurred in transforming cleanly and well-ventilated theatres into structures of tiles and glass was a necessary expenditure. It might be said that it was all in the right direction, but there were considerations worth bearing in mind before the money of a charity was expended in costly reconstruction. Smooth and impermeable materials were not necessarily those which were most easily rendered aseptic. It was a fallacy to suppose that a theatre was made aseptic by douching its floor with antiseptic solutions. The cleansing of a good, old wooden floor was perhaps antiseptically as satisfactory as the treatment applied to its modern substitute. But the emanations from spectators were more dangerous than those from walls and floor. Must we not, therefore, follow those who had cut the spectators off more or less by an impermeable but transparent screen? The emanations from the operator and his assistants were, however, far more likely to reach the wound than those from spectators. So we might picture to ourselves a time when every one concerned in an operation—patient, surgeons, and assistants—having been rendered from top to toe cutaneously aseptic, should cover each natural orifice of the body with an antiseptic mask, and, clothed in raiment scientifically pure, should pass into an atmosphere freed from germs by the air pump and by heat.

If the air was a negligible quantity—and if not absolutely it was very near it—it would be unfortunate that in cases of antiseptic failure the surgeon should be led to seek in unfavorable surroundings for a loophole of escape from self-blame, or to believe that he could not operate with perfect success save in a glass case or a crystal palace. Our ingenuity need not be directed to the air, which might be trusted to efficient ventilation, and the germicide action of the tissues. The skin, the instruments, the apparatus, were the true objects of our care.

Injuries of the Elbow-Joint.—Professor Bennett, of Dublin, then opened a discussion on this subject. Although such injuries were among the most common to which the limbs were liable, a good deal remained undefined and undetermined in their treatment and diagnosis. In the first place, the terminology of the parts affected was uncertain. Surgeons and pathologists on the one hand, and anatomists on the other, used different sets of terms for the points of bone about the joint, and surgeons were not agreed as to the use and meaning of those terms. One cause of difficulty in these cases was the rapid onset of swelling after the injury, which soon rendered diagnosis from external palpation almost impossible. Failure to recognize incomplete dislocation of both bones forward led to many cases of deformity and loss of usefulness. Then, again, the incompleteness of our knowledge of separation of the lower epiphysis of the humerus was to be regretted. As regarded swelling, the surgeon who saw the case after all swelling had subsided should take a charitable view of the mistakes of a colleague who had seen the patient only when swelling was at its height. There was in modern text-books a remarkable absence of references to incomplete dislocation of the forearm backward. Erichsen and Astley Cooper said that dislocation backward was easily recognized. This was true only of complete dislocation. The text-books in this respect misled surgeons. Incomplete dislocation was as frequent as complete. It was difficult to understand different authors' statements as to separation of the inferior epiphysis of the humerus, owing to the confusion of terms. In this injury two tumors would be felt, situated on the back of the elbow in a transverse line; but in dislocation backward of both bones, although there were still two tumors (formed by the olecranon and the head of the radius), these were situated in an oblique line, the inner one formed by the olecranon being the higher of the two. In compound separation of the epiphysis with protrusion of the end of the shaft, he agreed with Smith that the joint was not necessarily opened, and often it escaped. The speaker showed a cast from a case in which free suppuration occurred, yet the elbow-joint escaped. This was a very puzzling circumstance, as the synovial membrane extended above the epiphyseal line. He believed the explanation was that the shaft of the bone was pulled out of the end of its periosteal covering, as a finger was withdrawn from a glove, and that the periosteum was torn above the synovial attachment. The proper title for such an injury would be displacement of the diaphysis from its periosteal sheath. One saw exceptions to this in practice, in which the joint was opened, but they were not common and in experiments on the cadaver the same occurred. The speaker's views were illustrated by diagrams and by specimens from the cadaver, in which this injury had been artificially produced.

Dr. Roberts, of Philadelphia, said that he had found that ankylosis after fractures into the elbow-joint was due to imperfect reduction and fixation of the fragments. The consequent alteration in the shape of the articulating surfaces constituted a mechanical obstacle to mobility. After severe fractures mobility was promptly regained when the movements of the olecranon and radius on the humerus were not obstructed by bony deposits. Hemorrhagic effusions into the joint and adhesions were relatively unimportant as causes of ankylosis. The conservation of the normal angle between the lower end of the humerus and the ulna was of importance, because if this was much altered there was a loss of carrying-power. This "gunstock" deformity was caused by displacement of one condyle, causing valgus or varus of the part, just as in Ogston's operation for knockknee the condyle was slid upward and the angle between thigh and leg altered. However, in the elbow fortunately slight alterations of this angle did not affect the usefulness of the limb, but it was the surgeon's duty to restore anatomical symmetry as far as possible as well as usefulness. The method that he had found most effective and now generally employed was that of fixing the fragments with long nickelled steel nails. Occasionally deformity and limitation of movement were due not to imperfect reduction, but to imperfect fixation of the reduced fragments, so that they slipped out of position again. Nailing prevented this. He used special steel nails with a head, to which a handle fitted. With this handle the nail was thrust through the skin and into the bone; the handle was then removed and the nail driven home by means of a hammer. Meanwhile the parts were held accurately in position by an assistant. Common wire nails would do in an emergency, but they were not sharp enough and not tempered properly. Skiagraphs were most important to determine position of fragments and the direction in which the nails should be driven. The speaker showed skiagraphs of several cases after nailing, three long nails right across the joint in different directions being used in a severe case. In cases of doubtful nature an exploratory incision was advisable, and should be much oftener practised than was general. The best incision was one on the anterior outer aspect of the joint, turning up a flap of the biceps and supinator longus. The not quite fully extended position was that in which he generally put up his cases. In cases of stiffness and uselessness after fracture, he recommended refracture and replacement.

Professor Chiene said that there were three positions in which we could treat injuries of the elbow-joint. He used them all. When for any reason the recumbent position was necessary, he used the extended position with weight-and-pulley extension of the hand and forearm. In fractured olecranon with displacement of the fragment, he used the same position with elastic traction on a splint, but in fractured olecranon without displacement he put the forearm in a sling. All other cases he treated in the fully flexed position, using no pad in front of the elbow, but only a layer of lint to keep skin from touching skin. In this position the stretched triceps acted as a splint. In some cases also he bandaged the forearm to the chest, which thus acted as a splint, keeping skin from directly touching skin. Massage after one week, movement after ten days in all cases.

Mr. T. Bryant agreed with Professor Bennett's explanation of the escape of the joint in many cases of compound separation of the epiphysis of the humerus. In this injury, when not compound, effusion took place between the bone and the periosteum and made clear what had happened. He thought there was no need to remove the end of the shaft in the compound injury. The extended position was the best for examination of the elbow; the bony points and their relative situations could be best made out in that position. In a large number of cases the extended position was the best for treatment. In general, he endorsed Mr. Chiene's remarks.

Dr. Kennedy Dalziel said that fractures into the elbow were caused generally by falls on the outstretched hand. Such a fall produced either a Colles' fracture, a fracture or dislocation at the elbow, or an injury of the shoulder, according to the direction of the force and other circumstances. The force of the fall was transmitted upward and outward from the inner side of the capitellum through the lower end of the humerus, and fracture occurred in this line. Commonly the fragment was displaced upward and rotated, as shown by skiagraphs, so that the capitellar surface came to be applied to the fractured surface of the hu-

merus. There might be excessive formation of bone with resulting ankylosis, or there might be non-union. In the latter cases the disproportionate growth of the healthy inner condyle caused displacement of the forearm outward, and gunstock deformity followed. One-third of the cases of fracture at the elbow-joint in young subjects were of this nature. It was not displacement of the epiphysis, but a true fracture, and occurred only before puberty. Nailing he believed to be a correct method of treatment. He had wired the fragment, but this involved leaving a foreign body in the joint, which was not advisable.

Mr. C. B. Keetley could not agree with Professor Bennett as to cause of non-suppuration in compound dislocation of the epiphysis. He thought it scarcely possible for the periosteum to protect the joint in the manner suggested. A good deal would depend on when infection occurred. If, as he thought, this was generally due to some carelessness of a house surgeon or dresser a day or two after injury, then the joint cavity might already be shut off by adhesions. It was important to have a free exit for pus. It was remarkable how joints seemed to protect themselves. He quite agreed with Dr. Roberts that displaced bone was a great cause of ankylosis, but he disagreed with him as to the need of nailing. The objections offered to the use of wire he had never found valid in practice. Fragments were seldom completely detached from soft parts, and, moreover, the irregularities of the fractured surface would keep the fragments in place when once reduced. He would state it as an axiom that all fragments should be cut down upon at once and wired. In dislocation, if the head of the radius could not be reduced it should be removed. In a case in point, that of a boy of fourteen years, there was fracture of the external condyle. He cut down on it and found the detached condyle turned upside down and inside out, with the fractured surface toward the skin. He wired it with excellent result. Obviously no other treatment but exploration could have corrected this properly. Splints, massage, and passive exercises would all have been useless. He did not think the latter means of much value in any case. Patients would not submit to passive movement when it hurt them, but if the displacement was corrected they might be trusted to exercise the joint of their own accord. The head of the radius was often thought to be the cause of obstruction, but it was very easy to be mistaken. He related a case in point, in which the olecranon was found to be in fault instead, and a wedge was removed from it.

Mr. Jordan Lloyd said that fractures were often mistaken for dislocations. He believed that dislocations of the elbow were very rare. The majority of cases so-called were cases of cleavage fracture of the lower end of the humerus, usually caused by falls on the elbow. Fracture of the olecranon in the young was extremely rare. At ages under twenty-five the humerus broke instead. He explained by means of a diagram the manner in which the olecranon acted as a wedge and split the humerus. The direction of the force either outward or inward as well as upward determined which condyle suffered most. These injuries were often overlooked, because in doubtful cases examination under anæsthesia was not regularly resorted to or the *x*-rays were not used. Often we must defer diagnosis until swelling had gone. He deprecated haste and did not think nailing was to be recommended, partly because even the best of us were not absolutely certain of asepsis, and because excellent results could be obtained without nails. He thought it would be most unfortunate if this meeting sanctioned the idea that nailing should be the routine treatment. Mr. Chiene's plan of using the body as a splint was an excellent one. The speaker had also got good results by treatment in the extended position. Stiffness was often caused by passive motion. He did not believe in its usefulness. Far more harm was done by it than by too long rest, which allowed complete consolidation. He had seen the elbow immobilized for six weeks or more, with excellent results. There was a form of fracture of the olecranon in the adult, due to a fall on it with dislocation, which was difficult to reduce. He had already described this injury, which consisted of a narrowing of the sigmoid notch caused by incomplete fracture with crushing together of part of the joint surface of the process, the periosteum acting as a hinge. For this injury operation was needed to restore the sigmoid cavity.

Professor Bennett, in reply, said that immediate diagnosis was important. He deprecated the general use of nails and screws.

The President said that the difficulty of reducing and controlling small fragments rendered treatment often unsatisfactory. The position in which the fragments were easiest put and kept right was the most useful in treatment. He was astonished that massage had not been mentioned. He believed it to be most valuable in treatment, provided that the fragments were secured in position. Passive motion was useful if correctly applied after an interval, but it must be gently and discreetly used. By passive motion he meant flexing the joint as far as possible once in the morning and extension once in the evening; no more.

Intestinal Obstruction.—Professor Kocher, of Berne, then read a paper on intestinal obstruction. Out of 77 cases 26 were malignant, of which 24 were operated on, mostly by extensive resection. In 20 the patients were still alive. Localized tuberculosis of the gut was somewhat common in Switzerland. Of 90 cases of this he had operated in 18 cases by resection of the whole diseased part. In 16 the patients had recovered and 2 had died. He had operated on 6 cases of intussusception by resection of all the folds of gut involved. All the patients recovered, and in one only a fistula remained. Every case of obstruction should be submitted to the surgeon at once, that he might decide as to whether operation was needed, early operation being most important; but the surgeon should employ every means in his power besides operation, and one of the most valuable of these was consultation with a good physician.

Œsophagotomy.—Mr. Thelwall Thomas reported three cases of œsophagotomy for false teeth in the œsophagus. In the first case the patient died of tracheitis and laryngitis and heart failure, due, he believed, to frequent attempts with much force to remove the plate before the operation. The operation in this case presented no difficulties or drawbacks. The two other cases did well, he believed because there had been no violent attempts under chloroform to remove the plate. No such attempts ought to be made, but if the foreign body could not be moved by gentle traction œsophagotomy should be at once performed. He used a continuous suture to the gullet and left a glass drainage tube in the wound down to the gullet. To locate the plate a metal-ended probang should be used. A clean cut into the œsophagus should be made, large enough easily to extract the plate. The suture was similar to that usually employed in suprapubic cystotomy. He used a feeding-tube only if it was found that the mucous membrane had been lacerated.

Hepatectomy.—Mr. Mayo Robson, of Leeds, reported three cases of partial hepatectomy for malignant disease. He had operated on thirty-five cases of malignant disease of the liver and biliary tract. In only three of these was complete removal of the disease possible. One patient died four hours afterward; the other two recovered well from the operation, but died of recurrence a few months later. In the incomplete

cases some of the patients were much benefited by the operation, and in some cases of cholecystotomy in which the disease was considered to be malignant the patients recovered permanently, being apparently cured by the incision. It was difficult to explain these cases except on the ground that the diagnosis was wrong and they were not malignant.

The first case was that of a woman, aged fifty-four. She had a swelling which for twelve years had been supposed to be a floating kidney, but had produced no symptoms. Three years ago she had attacks of pain and vomiting and slight yellowness of skin, not amounting to jaundice. Six weeks before operation she had an attack of acute pain in the tumor on stooping. The tumor became tender and quickly increased, until the right lobe extended to the groin. Diagnosis was made of a large gall bladder, possibly due to malignant disease. At the operation the gall bladder was found to be adherent to neighboring parts and full of a putty-like material and some stones. This was cleared out with a lithotomy scoop. The entrance to the cystic duct was almost occluded by the new growth and by a gall stone. A nodule was found on the under surface of the liver, and he determined to attempt to remove this as well as the gall bladder. The parietal and visceral peritoneum was sutured at the margins of the wound, and two sterilized knitting-needles were thrust through the liver beyond the diseased portion and a rubber drainage tube was firmly tied round them. Such slight bleeding as there was yielded to sponge pressure. The projecting portion of liver was cut away. There was no bleeding from the stump, which was fixed in the wound. The needles came away on the fourteenth and twenty-first days respectively, and the ligature was removed at the end of a month. The tumor weighed half a pound without the putty-like material, and was an epithelioma.

The second case was also that of a woman, aged fifty-two. The symptoms were very similar and the same putty-like material was found in the gall bladder, which was enormous. There was a nodule on the liver, and the right lobe was drawn up out of the wound and an elastic ligature applied, as before. The disease was apparently completely removed. She recovered slowly, and suffered from ague-like attacks. The needles and tourniquet separated in fourteen days with a free discharge of blood, after which she had no more attacks of ague. The portion removed was about as large as in the first case. The patient died of recurrence some months later.

The third case was one of a large tumor. The disease was very extensive; there were two hundred and forty gall stones and putty-like material and much matting of the parts. He separated adhesions to the duodenum, colon, pylorus, omentum, and parietes, and performed the same operation as in the other two cases. He would also have done a pylorectomy, but the patient was too feeble. She died the next day.

There was a marked history of stones in these cases, but other symptoms raised the question of malignancy. It appeared probable that the irritation of gall stones started the epithelioma, and if so, that was a reason for early operation for gall stones. Granted that such a condition as he had described was found, the question arose: Was it worth while to do partial hepatectomy? He could not yet answer that question. In two similar cases he closed the wound after removing only the gall bladder in one, and doing nothing except examine in the other. Both patients suffered much more than the first two and rapidly died. He was therefore inclined to try partial hepatectomy again. Of course his remarks applied only to localized cancer spreading from the gall bladder. Other operators on the liver had controlled hemorrhage by raising flaps from it and drawing them together over the wound on it, by stuffing the wound with sterilized gauze, or by the application of compressed air heated to 300° F., or by hot steam; but when feasible the elastic ligature was the best means. The following were the speaker's conclusions: (1) Statistics having shown the association of gall stones and cancer, it was desirable to operate for gall stones earlier than had hitherto been usual; (2) all tumors of the gall bladder should be operated on; (3) if these rules were followed cancer would be less frequent, and (4) when it occurred would be treated earlier; (5) exploratory operations were worth doing, even although malignancy was feared; (6) if the disease proved to be too extensive for complete removal, he would do nothing and close the wound.

Dr. Roberts, of Philadelphia, asked whether Mr. Mayo Robson used drainage in these cases.

Mr. Robson said that this was a large and important question. He did not use a drain in these three cases, because all the disease apparently was removed and there was no oozing. Otherwise he would have used a very large rubber tube containing a gauze drain and leading down into the right kidney pouch, which held nearly a pint, and if this was drained no tube was needed in the middle line, unless there was much effusion. He would not dream of removing the primary disease if there was a secondary nodule in the liver, but he found that the surface of the liver could be very thoroughly examined through the wound.

Enterectomy. Mr. Rawdor read a paper on two cases of enterectomy after strangulated hernia, for which Murphy's button was used. The first was that of a man aged thirty-eight. The hernia occurred suddenly and was strangulated. After the ring was divided it was easily reduced, but ruptured while this was being done. He resected the gut and used Murphy's button. The other case was similar. Both did well, and there was no shock in either.

Mr. J. P. Bush described cases of gastric ulcer with perforation on which he had operated. In the first case, thirty-six hours after symptoms of perforation there was no loss of hepatic dulness. The stomach was covered with lymph. He explored the lesser cavity of the peritoneum and found an ulcer on the under surface of the organ. He used three rows of sutures, satisfied himself that the stomach was watertight, carefully sponged out the abdomen around, and closed the wound. He preferred sponging to irrigation. The patient was collapsed for the first twenty-four hours, the respirations being only 8 or 9 a minute. She then steadily improved, but three or four weeks afterward, when on solid food, she rose from bed, fainted, and died immediately. Post mortem the ulcer was found to be healed, and only slight puckering marked its site. There was no suppuration and the lungs and pleuræ were normal. Some would say that this was a case of septic poisoning. He believed it was heart failure.

In the second case, eighteen hours after the attack he found all the classical symptoms. Food, such as plums, caraway seeds, etc., came out of the wound. The ulcer was in front of the stomach, where a hard mass was felt. He used four rows of sutures, sponged well, and put in two drainage tubes—one to the ulcer and the other to the back of the spleen, where a collection of lymph was found. Nothing was given for the first twenty-four hours, and only water for the second twenty-four hours. He believed these precautions were most important. Recovery was uninterrupted and the patient was now well.

He thought these cases showed that irrigation was not necessary. He believed that it did harm; how much, he could not tell. It might cause the peritoneum to lose part or all of its power of dealing with septic matter, and no amount of irrigation could asep-

ticize the peritoneum in these cases. Early operation was most important as influencing results. Mortality was about fifty per cent. in cases operated on within twelve hours, but rose to ninety per cent. if all cases after twenty-four hours were included. If operations were done from four to ten hours after attack, the mortality would be very much diminished. The first case showed that when the ulcer was on the posterior surface the symptom of resonance over the liver, on which stress was laid, was not present.

The President suggested that the question of duration should influence the choice of sponging or irrigation.

Several other speakers urged that complete cleansing of the peritoneum by sponging was not possible, and much more injury would be likely to be inflicted by it than by irrigation with unirritating fluids, such as sterile saline solution, which also had the advantage of diluting such irritating fluids as the gastric juice and the brandy which friends or bystanders almost invariably gave in these cases.

Empyema.—Mr. W. Menzies Hutton read a paper on the treatment of empyema. This was admittedly unsatisfactory at present, especially in adults. Cures were generally incomplete, so far as expansion of lung was concerned. The longer a case took to heal, the worse the ultimate result. In adults tapping alone rarely cured, but it was useful as a preliminary to operation, because with the pleura distended with pus and the lung collapsed the voluntary muscles of respiration were needed to keep the patient alive. Chloroform took away this help, and most alarming or even fatal respiratory failure might occur before the lung could be relieved. A preliminary tapping removed this danger. Incision should be made along the sixth rib in the midaxillary line, the part where the lung last expanded. If the opening was behind or in front of this, it would be blocked by the expanding lung before expansion was complete. When the pleura was opened the action of the lung was reversed—it collapsed with inspiration and expanded with expiration. This was largely produced by the action of the sound lung, which in inspiration drew air through the bronchus from the opposite one. To help expansion of lung we must provide for exit of pus, while preventing entrance of air. The speaker showed the apparatus that he had devised; it consisted of a flanged rubber tube with a glass tube externally, within which was an ordinary rubber teat with a slit in the end. After applying this he found expansion hastened, the rate of respiration falling fast toward normal. Expansion generally occurred in eight days. Marked improvement appeared in three days in all cases. How long after collapse of the lung improvement was possible with this appliance he did not know, but he had seen it after eight months. If when the patient coughed air escaped from the sinus, there was good hope of improvement. The tube was contraindicated only when there was an opening into a bronchus. The tube should be only long enough to go through the chest wall. A piece of gutta-percha tissue with a hole for the tube was placed under the flange; this adhered to the skin closely.

Prostatic Hypertrophy.—Dr. H. Nicholl read a paper on the treatment of chronic enlargement of the prostate. There was no doubt of the necessity of operative interference in many cases, whether palliative or radical. Drainage was enough in some cases and might prove curative. After referring to his previous publication in *The Lancet* of April, 1894, on prostatectomy, he briefly described his method, which consisted in the enucleation of the prostate through the perineum, aided by pressure of the fingers introduced into the bladder through a suprapubic cystotomy wound—the entire operation being performed without opening the base of the bladder or the urethra, these being defined and thus protected from injury by the fingers in the bladder and a bougie in the urethra. The advantages of the method were (1) avoidance of contamination of the wound by urine; (2) adequate removal; (3) less hemorrhage; (4) avoidance of risk of tearing out portions of the neck of the bladder or urethra, and its results. In May, 1894, Dr. Alexander had published, at the meeting of the American Genito-Urinary Association, an account of a method in every respect identical with the speaker's except in one detail, viz., that Dr. Alexander drained the bladder through the perineum in all cases, while Dr. Nicholl did so in only a small proportion of cases and in no case until several days after the prostatectomy. The few cases that he drained through the perineum were those of a pedunculated median lobe and cases in which cystitis persisted, despite draining and douching by the suprapubic opening. In 1895 castration or vasectomy came into fashion for enlarged prostate. He had tried the method, with varying results. Further observation was needed to enable us to come to a decision. Many cases improved astonishingly without operation. Cases in point were related. These cases would, of course, give good results with any operation. Cases should be observed a longer time than had been usual before publication, and in any statistics those cases in which castration was declined should be published and also those in which it had failed to give relief.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MORE ECHOES FROM EDINBURGH—ROSS' DISCOVERY AS TO MALARIA—MISSIONS—TEMPERANCE—GRADUATION CEREMONY—MR. POWER.

London, August 5, 1898.

The most successful of all the sections was unquestionably the new one—tropical diseases. Not only from the tropics, but from all parts of the empire were gathered the members who had practised in various parts and were now in these islands. Not only so, but Americans and foreigners were attracted to this section, and the room where it was held was generally crowded by an enthusiastic assembly.

Dr. Manson, president, opened with an address. He was evidently suffering a good deal, and the next day was unable to be present. He is a victim to gout, and much sympathy was felt for him. The following day he was able to be present and give a lucid account of the recent remarkable work done by Surgeon-Major Ross, I.M.S., in tracing the rôle of the mosquito in spreading malaria. You will remember how, three years ago, Dr. Manson put forward the hypothesis that the mosquito is the extracorporeal host of the plasmodium. Surg.-Maj. Ronald Ross has been working at this subject ever since; step by step his discoveries have been continued, and he has raised the hypothesis to the dignity of a theory. So much was known, and Dr. Manson's lecture was looked forward to with pleasure. But it came as somewhat of a surprise that he should be able to announce the very latest discovery which Ross has made, communicated by telegraph that morning. This seems to be the crowning of the edifice, and evoked the utmost enthusiasm.

A congratulatory telegram from the section was voted at once to be forwarded to Surgeon-Major Ross.

The garden party given by Prof. and Mrs. Bayley Balfour in the Botanic Gardens was rather spoiled by the weather, as it took place on the only wet day of the week, but the host and hostess did all that was possible to entertain their numerous guests, although the

gardens could not be enjoyed as if there had been sunshine.

Sir T. Grainger Stewart found time to preside at the formal opening of the Medical Missionary Loan Exhibition. Sir Grainger is the president of the Edinburgh Medical Missionary Society, and it can therefore be understood that he was ready to do his best for that as well as for the larger association. This Medical Missionary Society has done much good work, and for many years Edinburgh, through its influence, has been the chief centre for promoting medical missions. The work began sixty years ago, with men like Abercrombie, Alison, and Chalmers, and has been carried on with zeal to the present time. One of the original members of the society, Dr. Moir, was present on this occasion, and said the president of the College of Surgeons had asked him to express his (the president's) great regret at being unable to come.

Dr. F. I. Mackinnon, a missionary of the society, from Damascus, gave an interesting address on the difficulties of the work in Turkey and the evident determination of the Mohammedan power to stamp out opposition by the sword as ruthlessly as it had first established itself by the same method.

Mrs. Bishop also spoke in favor of medical missions, which she said she had seen in almost every part of Asia and elsewhere pioneering the way and removing prejudices by their beneficent ministrations and invaluable hospital work.

The temperance breakfast, given to the British Medical Association by the National Temperance League, is now looked forward to as an annual function of no little interest. Over one hundred ladies and gentlemen attended it at the Edinburgh meeting Professor Simpson presided, supported by Dr. Whyte and a number of colleagues and others. Dr. Simpson said most of them were teetotallers on the Pauline principle—for the sake of their medical brethren.

Dr. Sims Woodhead, president of the Medical Temperance Association, said that though many, as Professor Simpson had remarked, abstained for the sake of others, they also knew it was for their own benefit, and though this might sound selfish it certainly entered into the calculations. He repudiated a statement attributed to him, that "alcohol as a drug is of no use." No medical man in his senses would say that. What he had said was: "If alcohol is a drug, it should be prescribed as a drug."

Dr. Clouston spoke of the effect of alcohol on the mental power, and said its first action in ninety-nine cases out of one hundred was to injure the mental working of the brain.

Dr. Ridge reported that there were four hundred and sixty or four hundred and seventy members of the Medical Temperance Association and some four hundred student associates.

Dr. Connel said he agreed with a recent declaration of Dr. Wilson that flogging was the thing for early drunkards. The guests separated after a very pleasant meeting.

There was an immense audience at the graduation ceremonial on Saturday. It was estimated that more than three thousand persons were present in the McEwan Hall the first time it has been used for medical graduation. The dignitaries of the university were there, and Sir William Muir, vice-chancellor, presided. The honorary degree of LL.D. was first conferred on a number of distinguished medical men. Some of them had already received this honor from other universities, and could therefore do very well without this. Then followed the conferring of the ordinary degrees on those who had passed for them.

Mr. Power, the eminent ophthalmologist, has met with a great sorrow. His daughter and granddaughter were washed off the pier at Whitby by a great wave and drowned, in spite of his desperate effort to save them. Every one feels the deepest sympathy with him in this sudden bereavement.

OUR BERLIN LETTER.

(From our Special Correspondent.)

WHY DOES THE HEART BEAT?—INFUSORIA IN CANCER OF THE STOMACH—TABES DORSALIS AND SYPHILIS—KOCH AND THE BUBONIC PLAGUE.

BERLIN, July 31, 1898.

RECENTLY at the Verein für innere Medicin quite a lively discussion was provoked by a paper of v. Leyden, on the innervation of the heart muscle. v. Leyden first presented a brief historical sketch of those discoveries which have thrown light upon the still unsolved puzzle, Why is it that the heart continues to beat uninterruptedly? The discoveries of the influence of the pneumogastric, the accelerator and inhibitory nerves, the cardiac ganglia, etc., tended to support the theory that the regulation of the heart's activity was effected through motor nerves whose centres are in the ganglia of the heart. Now, however, it has been observed that a heart which has no ganglia can beat, and this has led to the conclusion that this organ can continue its functions entirely independent of all nervous influence. This view is based upon the following observations: 1. The heart of the embryo pulsates long before any nerves at all can be shown to be present in it. 2. We have certain unstriped muscles in the body which are capable of contracting, and in which neither nerve fibres nor ganglia can be demonstrated; such, for example, is the muscular tissue of the ureter. 3. According to the latest researches of the younger His, the cardiac nerves come from the sympathetic, while the cardiac ganglia belong to the spinal system; and, these being purely sensory, the nerves of the heart must be so too, and are in consequence incapable of giving origin to motor impulses. 4. End bulbs have never been demonstrated in the heart, although it is established that all the muscle cells are surrounded by nerves. v. Leyden named especially Engelmann and His as defenders of this new theory, and Waldeyer and Kronecker as strong opponents. He said he was incompetent to decide the question. During the discussion, A. Fränkel observed that the new theory does not explain why peripheral irritation of the pneumogastric causes the heart to stop. Schwarz thought it possible that there may be certain connections between the heart and the ganglion cells in the embryo which our present methods cannot discover. Benda declared that the Engelmann theory rests upon as weak a foundation as the one which teaches the irritability of the striped muscles. No one denies the existence of the nerves of the heart; then what purpose do they serve? It is not probable that they are of a purely sensory nature, as claimed by His; for the spinal ganglia, from which the cardiac ganglia are derived, pass out from the medulla, which contains both sensory and motor fibres. The sympathetic cells in all likelihood act as true reflex centres, in that they receive sensory impressions and send out motor impulses. This idea of sensory and motor impressions and impulses passing alternately through the same nerve fibres is tenable, for it has long been known that double impressions pass along the same nerve fibres. No one present defended the theory of Engelmann.

Another recent theory, that of the parasitic nature of cancer, was again brought into discussion by Dr. Strube at a meeting of the Gesellschaft der Charité-Aerzte. He showed some infusoria which he found constantly in the gastric contents of a pa-

tient suffering from cancer of the stomach. There was no doubt at all that they had grown upon the carcinomatous mass. They were of an oval form, independently motile, and had three or four flagella attached to their anterior end. Some, however, appeared round and motionless; these could, by merely warming, be made to assume the oval shape and become motile. Classified according to their habits and mode of existence, they come under the head of flagellates, and belong to the genus Trichomonas, such as have been often observed in the intestinal contents at autopsies, and *intra vitam* in diarrhœal discharges. Strube held that any direct etiological connection between these parasites and carcinoma is out of the question, and his conclusion was supported by the report of Burghart, who observed them once in the diarrhœal stool of a phthisical patient and in the sputum from a case of abscess of the lung.

Virchow's words during the discussion of Silex's paper upon "Optic Atrophy in Tabes Dorsalis," read before the Berliner medicinische Gesellschaft, go to show what a vast difference there is between theory and fact. The grand old teacher hailed the syphilis enthusiasts with a vigorous *quos ego*. He could no longer observe in silence, he remarked, how the supporters of the syphilis theory in the etiology of tabes dorsalis gained one victory after the other, simply because no vigorous defence was any longer offered them. He saw the same story as that of aneurism repeating itself. At first it was mildly suggested; now a grand array of authorities openly support and defend the theory of a connection between tabes and syphilis. The same remarks would apply to general paresis. But such procedures are not scientific, he said, for, while it is possible that syphilis may be the cause of these affections, no actual proof has yet been brought forward. One condition which occurs so often in connection with constitutional syphilis, viz., amyloid degeneration, is almost never found in tabes. Of course the corpora amylacea are not here to be taken into consideration, for they are to be found in the spinal cord of all old persons. Virchow warned against too hasty conclusions. He was not opposed to a rational inunction treatment, which could do no harm. At present only the statements of the patients themselves support the theory of an etiological connection between syphilis and tabes; but Virchow did not regard it as impossible that real proofs might some time be found.

Another medical man of Berlin, Robert Koch, delivered an address before the Deutsche Gesellschaft für öffentliche Gesundheitspflege on his investigations concerning the "Spread of the Bubonic Plague." Koch called especial attention to the important part played by the rat, which is much more susceptible than man to the poison of the plague. He mentioned four plague centres where the disease never dies out; viz., Mesopotamia, the high mountainous regions of Thibet, the coast of Arabia, and a heretofore unknown spot in Central Africa. Koch was of the opinion that we need not be alarmed, for a study of the places and conditions in which the plague thrives teaches us that the latter can make no stand against our advanced civilization and culture. Already it has crept into the farthermost corners, and we may hope that the spread of civilization will drive it out of these corners even.

To Give to Cotton Thread the Smoothness of Silk.—Remove the fat with soda solution, wash in an abundance of water, dry and dip in colloidin (concentrated collodion) 5; alcohol, 50; sulphuric ether, 50. Sublimate (1–1,000) may be added.—GOUBAROFF.

THE CARE OF THE WOUNDED AT SANTIAGO.

To the Editor of the Medical Record.

Sir: Returning from Cuba a few days ago on board the *Segurança* in charge of sick soldiers, one of the first things to meet my eyes was a reproduction in the daily papers of an editorial from your columns attacking the medical department of the army. On this point I wish to say only a few words at present, and I hope to give more in detail later. I was at Siboney from the 27th of June until the 25th of July, and I think myself quite competent to speak concerning the treatment of the sick and wounded at that place, where the general hospital was located. Concerning the surgical skill of the operators at Siboney there can be no question. In the hands of such men as Le Garde, Nancrede, Parker, Fauntleroy, Ireland, and medical officers from our fleet, the wounded soldier had the best scientific treatment. As to general care of the wounded, I may say that, while this is my first experience in taking care of those wounded in battle, I do not believe that there ever was before an engagement as bloody and as prolonged as that of Santiago in which the wounded were so well cared for. Every soldier carried in his knapsack a first-aid package, and all had been trained more or less thoroughly in their application. Personally I distributed about twelve hundred of these, and quite a number of these same bandages came back to me on wounded soldiers. I can from personal knowledge testify to the fact that many lives were saved by their use. So far as I know, this first-aid package has not been so extensively used in any other war. For many wounds these dressings, applied by comrades on the fighting-line, were all that was needed until the injured man reached the hospital.

The transportation from the front to the hospital at Siboney was not what we wished. There were only a few ambulances, and most of the wounded were brought to the hospital in army wagons. Many men suffered severely during this ride. The intense heat, the cramped position of many in the crowded wagon, and the jolting of the heavy vehicle over the rough road, all combined to give discomfort. Why were there not more ambulances? They were left at Tampa or were not unloaded on the Cuban coast. The medical department was not, however, responsible for this. To provide transportation is the duty of the quartermaster's department, but I do not know that any one can be censured very greatly for the failure to provide a sufficient number of ambulances. It is well known that the transports were crowded, and the landing of animals and vehicles both at Daiquiri and at Siboney was a difficult and dangerous task. I was on a transport which approached the coast as nearly as the captain dared. When the anchor was dropped from the prow, the line went down forty fathoms, while the depth at the stern was only seven fathoms and not fifty yards away were the sharp rocks of a precipitous coast. It can be readily imagined that with high waves dashing against the ship such a position might quickly become perilous. Horses and mules had to be pushed into the water, and, while most of them swam ashore, some were drowned. Even the landing of men was not easy. We had to drop as best we could into row-boats, which at the time were being tossed up and down by the waves, and when the boats neared the shore they often became unmanageable and were filled with water. Like many others, I waded ashore. There are many, especially among those who stayed at home, who are ready to tell us of the great mistakes made in this campaign. They say that Shafter should have taken more time. He should have encamped on the shore and built good docks, so that everything on

board the transports could have been landed. He should have built good roads all the way from the landing-place to Santiago. He should have brought up heavy artillery. Soldiers should not have been allowed to charge fortifications and batteries without artillery support. These are some of the many things that we are told should have been done. I have no claim to military knowledge, and General Shafter did not consult me; but as a medical man I wish to say that in my opinion had half these things been attempted the Spanish flag would be to-day floating over Santiago and the American army would have been fortunate had one-half of it escaped both sickness and Spanish bullets. Enervated by heat and disease, the army could not have made two weeks later the glorious charge it did make on San Juan. Dock-building on Cuba's coast and road-making in its mountain passes at this time of the year would, in my opinion, have caused more deaths than were due to the great fight at El Caney. This is not altogether a matter of medical opinion. It is a fact that the regiment left at Siboney and between that place and Aguadores furnished the first case of yellow fever and suffered most severely from that disease. It is well known to students of epidemiology that yellow fever is most frequent and most virulent immediately along the shore. The fighting was practically over by the evening of July 3. On the 5th I saw the first case of yellow fever. Before that day had passed we had three or four more cases, the next day about thirty, and the next more than fifty; and all of these were among those working on the coast.

On the arrival of the wagons loaded with the wounded at the hospital at Siboney the men were placed as best we could. At the request of Dr. Le Garde, I superintended the placing of several trains of the wounded. It is true that there was not always a cot ready for the reception of each man, and those least seriously wounded had to lie on the ground for some hours; but we had blankets and made them as comfortable as possible. No one was neglected. Every one who could do so lent a helping hand. At least one newspaper reporter gave his time for days to feeding these men. I think that he furnished the food from his stores and prepared it himself. That it was good I can testify, because he brought me a cup of his broth late at night on more than one occasion. That no one was neglected I know, because on Dr. Le Garde's order I went with an orderly carrying a hypodermic syringe and tablets of morphine and strychnine late every night through all the tents, and ordered special attendants for those in need. Drs. Fauntleroy, Ireland, and others went through the tents more frequently and were untiring in their labors.

As to the lack of dressings and other supplies, I wish to say that, so far as I know, the charge on this score is as unfounded as is the general statement that the wounded were neglected. I never failed to find suitable and sufficient material for dressing wounds. We exhausted certain things. We ran out of iodoform gauze, but there was plenty of bichloride gauze. The Red Cross sent up a big box of dressing, for which Dr. Le Garde gave thanks in his big-hearted way so warmly that one of the officers of this society now tries to make it appear that without this aid the wounded soldier at Siboney could not have had his broken limb bound up. The absurdity of this is evident from the fact that medical officers from the *New York*, *Iowa*, and other ships of our fleet came over daily and worked at the operating-tables. Will any one claim that there were no surgical dressings on these ships?

VICTOR C. VAUGHAN, M.D.

Yellow Fever is said to prevail at San Juan, Porto Rico, but the report lacks official confirmation.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 20, 1898:

	Cases.	Deaths.
Tuberculosis	166	132
Typhoid fever	94	18
Scarlet fever	64	5
Measles	59	6
Diphtheria	98	13
Chicken-pox	6	0

Alcohol and the Russian Death Rate.—An official inquiry into the comparatively larger increase in the Tartar population of the city and government of Kazan has, according to the *Kamsko Volshki Krai*, brought out some remarkable facts as to the effect of alcoholic indulgence on the death rate. The Kazan Tartars, numbering about 640,000, have a rate of mortality of only 21 in 1,000, while the mortality among the Russians is 40 in 1,000. The general conditions among orthodox Russians and Mohammedan Tartars are practically the same, except in so far as personal habits are concerned. The medical investigation leaves no room for doubt that the lesser mortality of the Mohammedan Tartars is directly due to their abstinence from spirituous liquors, in which the Russians indulge freely.

Health Reports.—The following statistics concerning small-pox, yellow fever, cholera, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending August 20, 1898:

SMALL-POX—UNITED STATES.

EXPERIMENTAL RESEARCHES ON THE EFFECTS OF DIFFERENT ANÆSTHETICS.

BY W. H. THOMSON, M.D., LL.D.,
PHYSICIAN TO ROOSEVELT HOSPITAL,
AND
ROBERT COLEMAN KEMP, M.D.,
NEW YORK.

DURING the prosecution of experimental researches instituted by us on the effects of serum and of antitoxin injections upon the circulation of the kidneys, we soon were made aware that the employment of sulphuric ether as an anæsthetic produced a specific effect of its own upon the renal circulation, which had to be taken account of before any trustworthy conclusions could be deduced as regards the particular effects of the administration of antitoxins. This action of ether was so often and so uniformly demonstrated as a derangement of the circulation of the kidneys themselves,

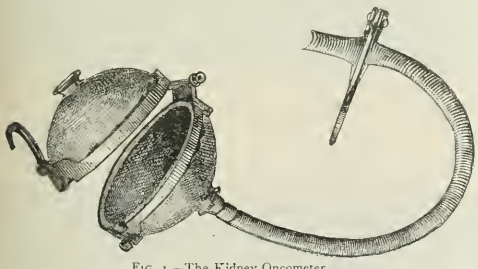

FIG. 1.—The Kidney Oncometer.

without a corresponding disturbance of the general circulation as indicated by the blood pressure in the carotids, that we concluded to institute a similar series of experiments upon the effects of other anæsthetics upon the kidneys. This subject is of such interest in connection with the relative effects of different anæsthetics upon different physiological functions that a brief account of the manner in which the experiments were conducted is herewith appended. We are indebted to the courtesy of Prof. John G. Curtis for the free use of the great facilities of the physiological laboratory of the College of Physicians and Surgeons for the experiments, the operations for which were performed by Dr. Kemp on dogs, along with check experiments upon rabbits.

The means by which the condition of the circulation of the kidney can be accurately determined is by an instrument first devised by Prof. C. R. Roy, of London, and called the kidney oncometer. Besides its extensive vasomotor supply, the kidney is so vascular that it has been estimated by Landergren and Tiegerstedt that when it is in full functional activity an amount of blood equal to the weight of the organ itself flows through it in a minute's time. Hence it is evident that great changes in its bulk would occur according to the state of its circulation, and this is so plainly demonstrated by the oncometer that even the rhythmical variations of blood pressure in the organ caused by the movements of respiration are recorded by it. As shown in the accompanying cut, the oncometer is a small, bivalved, kidney-shaped, metal box, hinged at the back, with a clasp in front, while a grooved notch at the centre of the rims of the valves prevents pressure on the vessels and nerves of the pedicle of the kidney when the organ is inclosed in the oncometer (Fig. 1).

Lying loosely upon the inner surface of the valves, but fastened to their rims by detachable metal bands, are two pieces of thin soft rubber, which when filled so allow a layer of water to be interposed between them and the metal walls of the box that when the two halves are shut down upon the inclosed kidney it rests upon a perfect water pad. A short metal tube in the centre of the upper valve, to which is attached a piece of soft-rubber tubing, allows the water in that lid of the oncometer to rise and fall in the tube according to the expansion and contraction of the inclosed kidney. This movement in the water column is communicated to a column of air farther on in the tubing, which in turn communicates with the air in a closed drum, or tambour, on the upper surface of whose diaphragm rests the long lever of the registering pen, which thus records the oncometric tracing upon a moving sheet of smoked paper. The use of water as the liquid in the oncometer pad is a great advantage over that of oil employed in Roy's instrument, both for convenience and for simplicity, and this improvement we owe to Mr. J. M. Hoyt, the practical electrician and machinist in charge at the physiological laboratory of the College of Physicians and Surgeons.

We give here (Fig. 2) oncometric tracings which illustrate the difference between normal and high-pressure curves. The lower tracing represents the lines made by a normal kidney, while the upper one shows the marked contrast when the renal vein is tied, for the consequent great venous congestion and swelling of the kidney in the box forced the water up the tubing so high that the resulting pressure in the air column threatened to burst the drum and raised the line of the tracings above the edge of the smoked paper. As in dogs the kidneys vary greatly in bulk according to the size of the animal, certain details are secured in Hoyt's apparatus for regulating the amount of water within the oncometer so as to make the pads perfectly adjustable to the kidney.

The secretion of urine was observed as regards rate, quantity, and quality during the experiments, by tying a small glass cannula in the ureter leading from the kidney which was not inclosed in the oncometer, so as to obviate the risk of the secretion being affected by the manipulation necessary to include the kidney in the box. We think that this requisite precaution has not been observed by some experimenters. The drops flowing from the ureter impinged upon a delicate lever with an oblique spatula-shaped extremity, the fulcrum of the lever being the drum of a tambour which communicated the stroke of the falling drops through an air column in a rubber tube to the drum of a second tambour, on which a lever pen registered every drop by a mark resembling an inverted V along a line on the smoked paper above the kidney-pulse

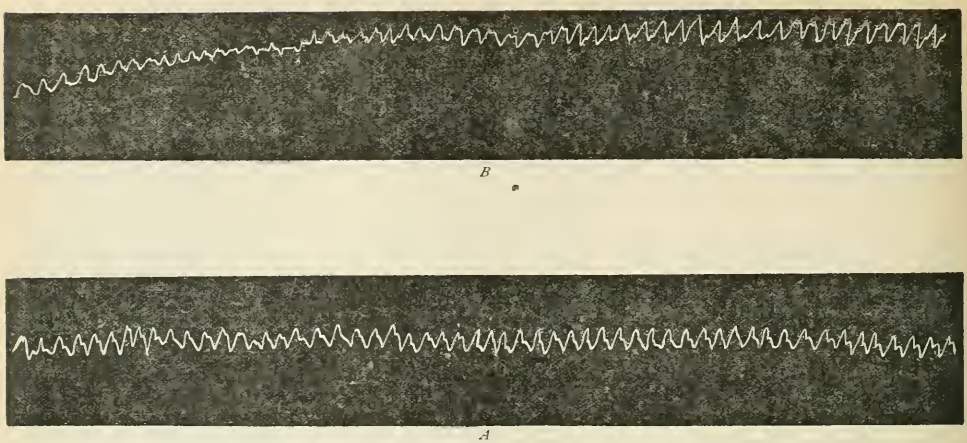

FIG. 2.—Normal and High-Pressure Oncometric Curves. *A*, Normal kidney tracing; *B*, tracing after ligation of the renal vein.

tracing. Meantime the drops of urine falling on the spatula end of the first lever flowed off into a cup, where they were collected for chemical and microscopical examination.

For the purpose of a constant comparison between the blood pressure in the kidney and the general blood pressure, a small glass cannula was introduced and tied in the right carotid, and to the cannula was attached a piece of rubber tubing, both it and the cannula being filled with a soda solution to prevent blood clotting. The rubber tube was then attached to a flexible lead tube, which was connected with a Ludwig's mercurial manometer, so that every pulsation in the carotid was communicated through the soda solution to the mercury in the manometer. A float on the mercury in the manometer carried a fountain-pen attachment, which registered the carotid pulsations with ink on the paper of the revolving, or Ludwig's kymograph. The normal height of the blood pressure was first carefully noted in each dog. This height varied from one hundred and twenty-five to one hundred and fifty millimetres, and, the standard height in each animal being thus noted, variations from this could then be readily observed.

To insure uniformity in the administration of the anæsthetic, as well as to have ready recourse to artificial respiration when needed, a preliminary tracheotomy was performed in all cases. The tracheotomy tube was tied in firmly, and to it a piece of soft-rubber tubing was attached, and the anæsthetic was administered through this tube.

In all such experiments, and notably in regard to the action of anæsthetics, a chief indication is to avoid delay as much as possible, for prolonged anæsthesia with any agent induces modifications from the first effect. In these operations it was found possible to complete all the incisions and make the connections between the different parts of the apparatus, with proper

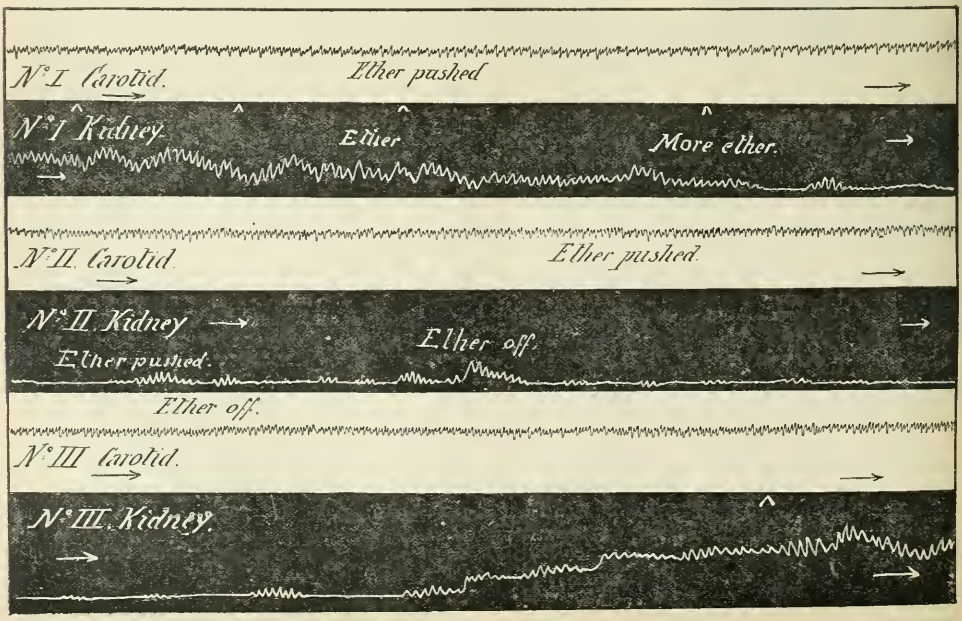

FIG. 3.—Oncometric and Carotid Tracings Following the Administration of Ether.

regulation and starting of the tracings, in twenty minutes.

Effects of Ether.—The results from the administration of ether obtained from experiments on ten dogs were remarkably uniform, and are well illustrated in the accompanying cut (Fig. 3).

Carotid tracings. The effect of ether on the general blood pressure as shown by the carotid tracings is to raise the pressure from the beginning, even under mild anæsthesia. When the ether is pushed the carotid tracings rise again slightly. When the ether is removed there is a moderate fall.

Kidney tracings. Under moderate anæsthesia there is at first a slight rise of the tracings from the base line, corresponding to the carotid tracings, but as the ether is pushed a marked contrast from the simultaneous carotid tracing is noted by a great fall in the oncometric curve, down to the base line and even below it. If the anæsthetic is thus kept up, the waves grow progressively shorter or even disappear for a few seconds. If the ether is then suspended it takes from thirty seconds to two minutes for the kidney to recover, when the tracing-line begins to rise again, to be again depressed if ether is readministered. This effect was noted over and over again, and from its uniform contrast with the corresponding carotid tracing it shows that this effect upon the kidneys is specific, and, what is more, this specific effect can be separately noted when ether is mixed with other anæsthetics.

The renal secretion under ether, determined as above described, was first an early diminution in the number of drops from the cannula in the ureter. The secretion diminished progressively as the oncometric curve dropped toward the base line, until finally, under free and continuous etherization, a complete suppression occurred. These are shown in the figure, "inverted Vs," on the upper line—three drops before ether was pushed, with only two drops in about four times the intervals afterward, and only one drop toward the end of the tracing. Albumin appeared early even under moderate anæsthesia. This increased under deep narcosis, until just before suppression it amounted to about sixty per cent. in volume.

Chloroform.—The experiments with chloroform were performed on six dogs.

Carotid tracings. As seen in Fig. 4, there is an evanescent rise, lasting only two or three seconds, when but a slight amount of chloroform is administered, soon followed by a fall of pressure. As the chloroform is pushed there is no initial rise, but the fall becomes more marked. As soon as the chloroform is suspended the pressure rises again. There can be no question that the fall is due to the depressing effect of chloroform upon the heart.

Kidney tracings. In contrast with ether, the kidney tracings closely correspond with the simultaneous carotid tracings. The kidney tracings become shorter as they approach the base line, but they do not become abolished, nor do they ever fall to the base line as with ether, but simply remain parallel to the record of the general circulation.

The renal secretion remains copious in amount, and begins to diminish only as the general circulation becomes much depressed, the urine continuing to flow nearly to the time of death.

Albumin appeared only after prolonged narcosis, and then in but small amount, though the general circulation had become dangerously lowered.

A.C.E. Mixture.—The anæsthetic known as the A.C.E. mixture is composed of alcohol, one part (by volume); chloroform, two parts; and sulphuric ether, three parts. This was tried by us on four dogs.

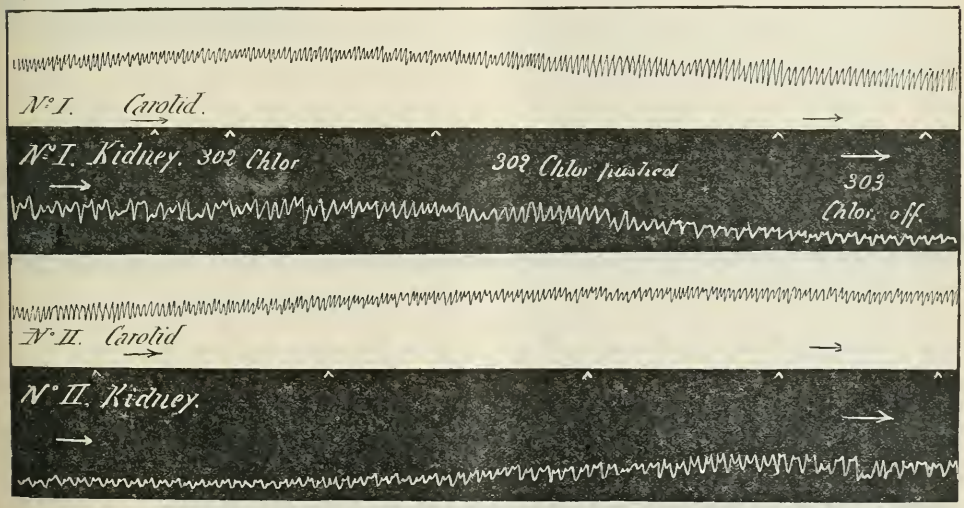

Fig. 4.—Oncometric and Carotid Tracings Following the Administration of Chloroform.

Carotid tracings. If administered by the open method, with ninety-five per cent. air, the carotid tracings are wholly similar to those of ether. If semiclosed or closed, a very pronounced chloroform effect. This is clearly shown in the carotid tracings of Fig. 5, in a dog in which it was administered by the semiclosed method and but a moderate amount used, for only a few seconds.

Kidney tracings. If this anæsthetic is administered by the open method, as above noted, ninety-five per cent. air, the kidney tracings are the same as those of chloroform. But when the semiclosed method are used, the tracings immediately become like those characteristic of ether. As there is less ether, however, in the mixture, the kidney circulation when the anæsthetic is suspended recovers sooner than when pure ether is used.

The renal secretion is more copious than with pure ether, but less than with chloroform. When the A.C.E. is pushed the secretion is diminished, but never to actual suppression. Albumin likewise appears early, though not so early as with pure ether, but in larger quantity than with chloroform. The inference, therefore, seems legitimate that with this mixture the effects

will be those of the inhalation of chloroform alone when the air is freely admitted, but that when the proportion of air inhaled is diminished by the semi-closed method we then get the specific ether effect upon the kidneys, along with an increased chloroform effect upon the general circulation.

Schleich's Mixture.—Three solutions or mixtures are used by Schleich. No. 1: Chloroform, 1½ oz.; petroleum ether, ½ oz.; sulphuric ether, 6 oz. No. 2: Chloroform, 1½ oz.; petroleum ether, ½ oz.; sulphuric ether, 5 oz. No. 3: Chloroform, 1 oz.; petroleum ether, ½ oz.; and sulphuric ether, 2⅔ oz. All these solutions were employed with four dogs, with like results, differing only in degree.

The carotid tracings in Fig. 6 show the effects of No. 3 solution, and are seen to correspond to those of the A.C.E. mixtures.

The kidney tracings follow those of ether, or rather, appear to occupy a position between those of pure ether and those of the A.C.E. mixture, being more pronouncedly like the ether effects than in the A.C.E. tracings. The recovery of the kidney circulation on the suspension of the anæsthetic took place rather sooner than from pure ether, but longer than after the A.C.E.

interference with the respiration. The ether, chloroform, A.C.E., and Schleich anæsthetics showed no variation from their previous results respectively, whether in the carotid or in the kidney tracings. Two dogs were used with such anæsthetics.

Nitrous Oxide.—This anæsthetic was administered during our experiments upon three dogs, by Mr. Hasbrouck, who has the greatest experience in the use of nitrous oxide of any one in the city. Owing to the special effect upon the respiration by this agent, the general blood pressure is shown (Fig. 7) in the carotid tracings to be rapidly and markedly raised.

These results are closely parallel to those of asphyxia, and are accompanied by a good deal of struggling, during which the excursions of the kymographic tracings are seen to be more pronounced than with any other anæsthetic. There is no depression of the heart until the respiration becomes much affected by pushing the narcosis, as was noted twice when artificial respiration had to be resorted to. When this anæsthetic was suspended the heightened blood pressure fell to normal very rapidly, and quick recovery was noted when artificial respiration was employed.

Kidney tracings. These are rather peculiar in some

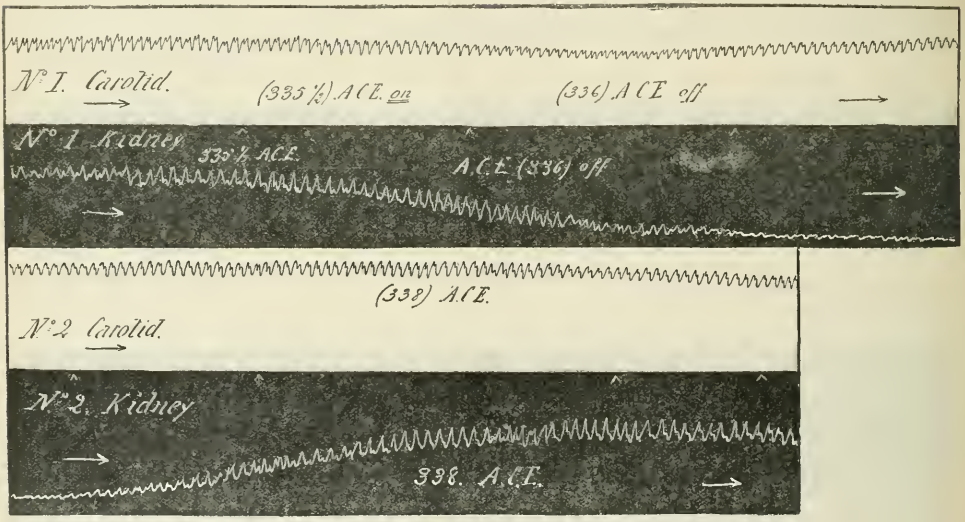

Fig. 5.—Oncometric and Carotid Tracings Following the Administration of A.C.E. Mixture.

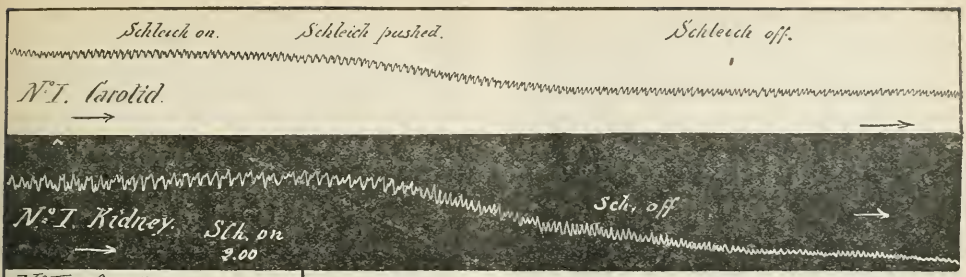
The renal secretion was diminished much more than with the A.C.E., though not quite to complete suppression. Albumin appears quite early, and with deep narcosis increases largely in amount, more than with A.C.E., but less than with pure ether.

In order to guard against error of interpretation of the oncometric tracings, as they might be in part affected by the movements of the diaphragm and of the abdominal viscera during respiration altering the position of the kidney or the proper alignment of its pedicle, it was proposed to eliminate all such muscular effects by the use of curare. For this purpose several drops of a one-per-cent. solution of curare, or one or two drops of a three-per-cent. solution, were injected into the jugular vein. Artificial respiration was then resorted to every few moments to keep up the action of the heart, but the respiratory movements were suspended while the effects of the several anæsthetics were noted. In these observations no difference was noted from the respective effects of the different anæsthetics upon non-curarized dogs, except such as were due to the general depression of the circulation by the

of their features, but are explicable as dependent upon the kidney sharing in the effects of interference with the respiration and consequent general arterial contraction, as shown in the carotid tracings. Under moderate anæsthesia the oncometric tracings at first fall, keeping close to and parallel with the base line. At this stage the oncometric respiratory curves are very pronounced, while the vertical tracings, *i.e.*, of the kidney pulse, are very short. If the anæsthetic is then pushed, the kidney waves disappear and the general tracing falls below the base line. These changes are very evanescent, and as soon as the anæsthetic is suspended the line rises again and the respiratory curves reappear, with a prompt return afterward to normal conditions.

The evidence, therefore, points to a contraction of the renal vessels corresponding in every particular with the general circulatory change, and not indicating any specific effect upon the kidneys.

Renal secretion. This is rapidly diminished, as might be expected from the fall in the kidney tracings. In complete narcosis some albumin appears, but it is



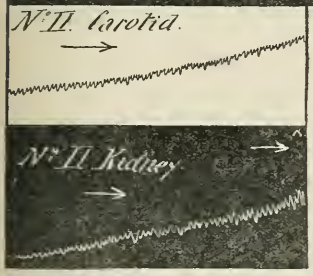


FIG. 6.—Oncometric and Carotid Tracings Following the Administration of Schleich's Solution No. 3.

moderate in amount, and soon disappears after the administration is suspended.

Conclusions.—As regards ether, it would appear that this agent produces a special contraction of the renal arterioles, with a consequent damaging effect upon the renal secretory cells, similar to those which follow clamping the renal artery. The kidney shrinks in bulk, with consequent fall of the oncometric tracing, and accompanied by diminution of secretion, marked albuminuria, and, finally, suppression. As remarked before, this condition of the kidney is not due to any change in the general arterial circulation.

These facts would seem to contraindicate the use of ether as an anæsthetic when renal disease is present, and particularly when with albuminuria there is a tendency to pulmonary œdema.

The effect of chloroform upon the kidney seems to be *nil*. The oncometric curves are nearly normal and are affected only through sharing in general circulatory changes. The secretion of urine continues up to the last moment of life, and the albuminuria is so slight that its presence at all is apparently due only to respiratory interference. Meantime the action of chloroform on the heart, as shown by the carotid tracings, is directly depressing. Ether, on the other hand, shows evidence of cardiac stimulation throughout.

The A.C.E. mixture shows the special effects both of ether on the kidneys and of chloroform on the heart, either being predominant according to the mode of the administration. If a large percentage of air be simultaneously inhaled, as is the case when chloroform alone is administered, the effect is that of chloroform cardiac depression without the effect of ether upon the kidney. If, however, the A.C.E. mixture be administered more as ether is when used alone, then a study of the carotid and kidney tracings shows clearly that we have both the cardiac depression of chloroform and the renal derangement of ether combined. This seemed to cause such powerful effects upon the breathing and upon the heart that artificial respiration had to be resorted to in every dog to which this mixture was freely administered, which was not the case with either ether or chloroform. As far as our observations go, therefore, we fail to see any advantage in this mixture of chloroform and ether, but rather the reverse.

These objections appear to be still more applicable to Schleich's anæsthetic. The cardiac depression of chloroform and the renal disturbance of ether are simultaneously developed in the tracings, similar to, but to a greater degree than with the A.C.E. mixture. Schleich claims that mixtures of different anæsthetics of different boiling, *i.e.*, maximum evaporation, points, are safer than the administration of the anæsthetics alone, on the assumption that the absorption of an anæsthetic as to quantity depends upon its boiling-point. The more volatile an anæsthetic is, the less will be absorbed into the blood in a given time.

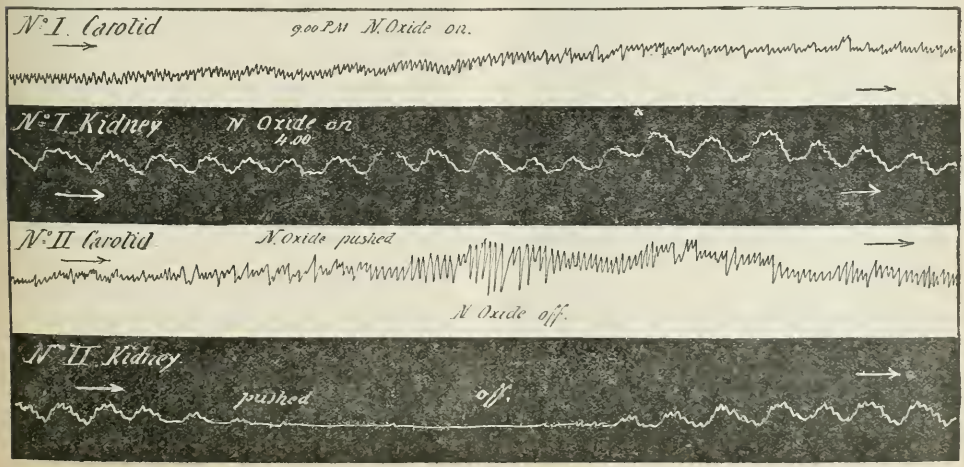

FIG. 7.—Oncometric and Carotid Tracings Following the Administration of Nitrous Oxide.

Hence ether, whose boiling-point is 93° F., will not be absorbed so rapidly as chloroform, whose boiling-point is 143° F. If, therefore, an anæsthetic could be produced whose boiling-point was the same as the normal temperature of the blood, the exact amount absorbed with each inspiration would be eliminated by each expiration. By causing the mixture to be at different degrees above this point, he claims that we can regulate at will the excess which the expiration would not remove, and thus the amount of the anæsthetic retained in the blood. His addition of petroleum ether or benzin to sulphuric ether and chloroform was further to facilitate the formation of a mixture or solution of anæsthetics which would afford a safer means of absorption.

We believe that practically this reasoning is fallacious, because it assumes that these mixtures or solutions constitute a new chemical homogeneous compound which will always be inhaled as one substance in definite chemical proportions, just as a compound salt is one substance when swallowed after solution in water; whereas the fact is that ether remains ether and chloroform stays chloroform during the inhalation, and that the proportion of either which will be absorbed will depend upon the mode of administration, a tight cone allowing an amount of chloroform to be taken which would be extremely dangerous, while the free admixture with air would so lessen the absorption of ether that its specific effects would be proportionately lessened. Meantime the adoption of benzin is not the adoption of an anæsthetic, for Dr. S. T. Meltzer, in a communication to us on his experiments upon rabbits with petroleum ether, by inhalation through mouth and nose, as well as through a tracheal cannula, says: "Petrol ether is not a narcotic. If a rabbit was put under deep anæsthesia by ether, and then ether suspended and petrol ether administered, the lid reflex soon reappeared and the rabbit woke up. The inhalation of pure petrol ether alone soon brings out a distinct tetanus and opisthotonos, to which the animal soon succumbs if the inhalation be continued. If the inhalation be discontinued at the appearance of the convulsions, the animal survives the tetanus, but this is then followed by a distinct paresis of all the extremities. If ether is given with the petrol ether, the tetanus movements are suspended, but not so the paralytic after-effects; the rabbit dies of paralysis of the respiratory muscles."

There is, moreover, a physical reason for doubting the manageability of mixed anæsthetics, due to the fact that if two agents of different maximum points of evaporation be mixed together, the more volatile of them will increase the evaporation of the other, by carrying off more of the less volatile one than if the latter were vaporized by itself. Thus more chloroform would be inhaled if mixed with ether than if it were administered separately.'

That Schleich's mixtures have been used in a number of cases without dangerous effects is no evidence that they are safe, for the same may be said of chloroform and of ether the world over. Mixed anæsthetics of any kind might be employed in hundreds of instances without unpleasant results, though actually they were more dangerous than unmixed agents, for with chloroform itself surgeons have published reports of ten thousand administrations of it without one serious accident.

CLINICAL STUDY OF INTERSTITIAL NEPHRITIS, WITH METHODS OF DIAGNOSIS.[1]

By EVERETT J. BROWN, M.D.,

DECATUR, ILL.

Bright's classical picture of chronic nephritis, so familiar to us all and so easily recognized, is about as follows: Universal dropsy with swollen face and puffed eyelids, profound anæmia, great weakness, shortness of breath, headache, diminished urine, which is loaded with albumin and tube casts, and finally the occurrence of uræmia, convulsions, and death. The diagnosis of such cases presents no difficulty, even to the medical student, but I wish to speak to-day of a form of chronic Bright's disease which is far more difficult to recognize and is of infinitely more importance to the practitioner, from the fact that it is of such common occurrence. I refer to chronic interstitial nephritis—a form of Bright's disease which often exists for five to ten years without being recognized. The subjects of it may have the appearance of perfect health, often of ruddy face and fine physique, and they are pursuing their regular occupations without interruption; they have no dropsy or puffed eyelids; they are passing an abundance of clear and what they call "healthy-looking" urine. It seems hardly necessary to examine it, they say; but when we do, what do we find? No albumin, or only a trace; acid reaction. Repeated examination shows no tube casts; the specific gravity is a little low, but it is easily accounted for by the amount of fluids ingested, or other cause. The cervical headache, the vertigo, and the indigestion are referred to errors of diet, and the patient is given blue mass and digestive remedies and told to regulate the diet, and then allowed to depart, while the slowly advancing, deadly contraction of his kidneys continues, until the end comes suddenly in the form of a uræmia or the slower but now easily recognized dropsy and heart dilatation. Many of these cases successfully pass through the hands of careless life insurance examiners, and are able to realize on their policies several years before their age of expectancy is reached.

How, then, is this form of nephritis to be early recognized, for upon early recognition depends the only

[1] Mr. J. C. Minor, Jr., a chemist of this city, has made careful researches on this point, and conclusively demonstrates this fact in the following statements:

"In my experiments Schleich's solution No. 3 was made up as follows: Chloroform, 60 c.c.; petrol ether, 30 c.c.; sulphuric ether, 160 c.c. The boiling-point of the chloroform used was 142°; of the sulphuric ether, 97°. Petrol ether was not constant, but ranged from 95° to 131°, most of it coming over between 104° and 113°.

"The chloroform was subjected in the distilling-apparatus for half an hour to a temperature ranging from 100° to 110°, and then for half an hour from 110° to 135°. Not more than 1 c.c. was vaporized at these temperatures in this time.

"Schleich's solution was then distilled and the distillate divided into three portions: *A*, boiled between 100° to 113°, gave 41 c.c.; *B*, boiled between 113° and 131°, gave 110 c.c.; *C*, boiled between 131° and 145°, gave 45 c.c.

"Fraction *A*, 41 c.c., was redistilled and gave three fractions as follows: *a*, boiling-point 100° to 110°, gave about 10 c.c.; *b*, boiling-point 110° to 118°, gave about 11 c.c.; *c*, boiling-point 118° to 136°, gave about 12 c.c.

"Fractions *b* and *C* were united and distilled in two fractions, the second of which, about 4 c.c., was almost pure chloroform, and boiled from 141° to 142°.

"Fraction *B*, 110 c.c., boiling-point between 113° and 131°, was distilled into four portions: (1) boiling-point 104° to 113°, gave 15 c.c.; (2) boiling-point 113° to 122°, gave 30 c.c.; (3) boiling-point 122° to 131°, gave 25 c.c; (4) boiling-point 131° to 143°, gave 30 c.c.

"No attempt was made further to treat the first three portions. Note on refractioning gave 18 c.c. of chloroform, boiling from 140° to 142°.

"It will be observed that the boiling-point of the greater part of the mixture was lowered, as claimed by Schleich, considerably below that of chloroform, *i.e.*, between 113° and 131°. But that any diminution thereby of the effect of chloroform is not to be expected, but rather the reverse, is evident from the fact that whereas a large amount of chloroform, as such, was found after vaporizing the portion between 113° and 131°, but a small amount was vaporized from chloroform alone under the same conditions of time and temperature."

[1] Read before the District Medical Society of Central Illinois, April 26, 1898.

hope of prolonging life? The diagnosis of interstitial nephritis is not a sentence of death by any means, for, although a very serious and often fatal disease, it is not incompatible with long life and apparent good health. One of our most noted statesmen when a candidate for the Presidency had had this form of kidney disease for many years. A large number of such persons live indefinitely and die of some intercurrent disease, and the post-mortem offers the first evidence of the diseased kidneys; in other cases the nephritis may exist for many years without symptoms up to a certain point, and then the patient becomes suddenly ill and may quickly die with uræmia; other cases gradually develop a cardiac hypertrophy, with a lowering of the specific gravity of the urine and a pulse that is easily made too tense; otherwise their health is good. They go along this way for years, and may die of some other disease. Another class of patients have attacks of spasmodic dyspnœa at occasional intervals, between which attacks they are well; later these become more and more severe, the heart compensation fails, dropsy develops, the shortness of breath continues day and night, the patient cannot lie down, and death comes to his relief. I have seen some cases with an onset exactly imitating an acute bilious attack, with vomiting and headache and constipation or slight diarrhœa; such a case I saw recently in consultation, and it is especially interesting as showing the great danger of delay in recognizing the true nature of the attack. I here give the history:

Dr. M——, aged thirty-five years, had always had a most persistent constipation; often headache. Had known that his urine contained albumin at times, but he continued to eat heartily of a full mixed diet, with plenty of butcher's meat. The present attack came on suddenly with severe headache and vomiting. It was regarded as a bilious attack and was treated with calomel and salines; no relief followed. The headache made him almost maniacal, and he rolled and tossed in bed with constant vomiting. An examination of the urine was now suggested, and it was found to contain both albumin and casts. By this time he was in a semicomatose and delirious state, with a rapid pulse, but no fever. Means for the elimination of the excess of waste products in his blood were used, consisting of cathartics and diaphoretics, with hot baths and packs. There was slight improvement, but on the fourth night he developed a temperature of 104.5° F., and a pulse of 140, with more profound stupor and delirium. It was thought that death was certain, but after reduction of temperature by cold pack and later a free catharsis with compound jalap powder, he gradually improved and was able to be up in a week.

Some cases show a most rapid development of fatal symptoms, coming on during apparently good health, or suddenly following some injury, or an intercurrent disease, or a surgical operation, especially if ether has been the anæsthetic used; in these cases cerebral symptoms predominate. There are dyspnœa, vomiting, general convulsions, coma, or a hemiplegia like that with a cerebral hemorrhage or embolism. The patient may be found on the street, in his room, or in bed, at first stupid and muttering incoherently and then completely comatose. Such a case I saw recently in a man picked up in an unconscious condition on the street. He was fifty-five years of age, and had not been very well for two or three years, although kidney trouble had never been suspected. Although he was unconscious, no paralysis was noted; he was breathing stertorously and was totally comatose. By means of a catheter a little urine was drawn and found to be albuminous and to contain casts. Physical examination of the heart showed cardiac hypertrophy without valvular disease. From the family I elicited a history of nocturnal polyuria, dyspepsia, headache, and vertigo, which left no doubt in my mind as to the cause of the fatal illness.

In cases following some injury or a surgical operation the patient becomes feeble, the heart is weak, the urine quickly becomes scanty or is suppressed, and the patient soon dies, or he may linger for a few weeks or even months in a condition of chronic uræmia resembling a mania or dementia, from which, however, he may finally recover. Such a case was the following:

Mr. C. H——, aged sixty-two years. Diagnosis, interstitial nephritis following an old stricture of the urethra. The stricture had led to atony and dilatation of the bladder and ureters with incontinence of urine. Under chloroform perineal section for division of stricture and drainage was performed. For three months the man's life hung by a thread on account of the uræmia which developed. He had stupor, delirium, and acute mania; the urine diminished to four or five ounces a day for a few days, but he finally recovered, with no recollection of about ten weeks of his illness. He is now actively engaged in the practice of his profession. The nephritis still existing is kept in abeyance by proper diet and mode of life. A recent examination of his urine gave the following result: Amount in twenty-four hours, seventy ounces; specific gravity, 1.012; acid reaction; amount of urea, four hundred and twenty-five grains; faint trace of albumin.

The great dyspnœa which occurs in paroxysms in some cases of interstitial nephritis is often mistaken for asthma and treated as such. The following case is an example of "renal asthma":

John McG——, aged fifty-five years, for two years had had frequent attacks of spasmodic dyspnœa, which occurred mostly at night and exactly imitated a bronchial asthma; the frequent attacks had caused considerable emphysema. He obtained no relief from the usual inhalations for asthma and only slight relief from hypodermics of morphine and atropine. A urinary examination revealed albumin and casts, and the heart showed hypertrophy with beginning failure of compensation. An exclusive milk diet with other treatment rendered the attacks less severe, but he finally died of dropsy and exhaustion.

With cases which are first seen in a comatose state, many mistakes are made and patients allowed to die when they would have recovered by proper treatment. Three years ago I saw in consultation a woman, aged fifty-five years, with supposed "brain fever." She had been practically comatose for two days, but could be aroused slightly by shaking and made to swallow a little nourishment. She had passed no urine since the beginning of her illness. With a catheter a little concentrated, highly albuminous urine was withdrawn, and a diagnosis of nephritis and uræmia made. Treatment by means of a hot pack, croton oil on the tongue, and hypodermics of pilocarpine caused a rapid elimination of urea, and the patient returned to consciousness after a few hours. Since then she has been practically well except for her chronic nephritis, which is held in check by proper diet.

Another common error is the mistaking of uræmia for hysteria. Such mistakes do the patient great injustice and often sacrifice her life, as the following history shows:

Mrs. B——, aged twenty years, pregnant two months, began suddenly to have "nervous spells" and then convulsions. These were treated for forty-eight hours as hysterical paroxysms, when an examination of the very scanty urine revealed the true nature of the disease. The patient died a short time after an induced abortion, which was performed by her physician in the hope of relieving her.

Many cases of interstitial nephritis are called and

treated as neurasthenia. Dercum[1] has recently called attention to this. He says: "A supposed neurasthenia may possibly be an obscure case of interstitial nephritis, in which it is necessary to make repeated search in the urine to find the proof." Professor Dujardin-Beaumetz[2] says: "How many cases of death unexplained have resulted from interstitial nephritis? How many diseases have deceived the physician as to their true nature and have been dependent exclusively on renal cirrhosis? The number is greater than you would suppose, and such mistakes, constantly committed, result from the fact that physicians have always been in the habit of referring for the diagnosis of chronic nephritis to Bright's description, and have an idea that it is necessary in order to be warranted in diagnosing this affection to have general œdema and scanty urine, which must be very albuminous. When these symptoms are not found they seek elsewhere for the cause of the disease and ascribe it by turns to other organs."

Contracted kidneys are more often found in men than in women, and the age is usually over forty years, although many cases are recorded as occurring in children. Of the sixteen cases constituting this report, eleven were in males and five in females; the youngest patient was twenty-four years and the oldest seventy-one years. Five cases occurred in the third decade, none in the fourth, five in the fifth decade, four in the sixth, and one in the seventh.

The increased amount of urine passed is usually the first symptom noticed by the patient. In six of the cases above mentioned in which frequent daily measurements of urine were made, the average daily amount for thirty-six observations was sixty-six ounces; the maximum passed in one day of twenty-four hours was one hundred and twenty-eight ounces and the minimum was forty-eight ounces. In one case, that of a woman, aged fifty-six years, in which nineteen measurements were made, the average daily excretion was sixty-four ounces; the minimum being forty-two and the maximum eighty-eight.

No disease is more insidious in its approach than is interstitial nephritis, and, as I said before, it may have existed for years, and give its first intimation in the shape of a profound uræmia. Some obscure symptom may lead us to an examination of the urine, such as arising at night to urinate, or a tense, bounding pulse, or a too strong impulse of the heart against the chest wall; or there may be a slight puffiness of the ankles, noticed only at night and evidenced only by the shoe being a little too tight. Often the patient has a feeling of unaccountable weakness or of being so often tired. The heart soon shows signs of a hypertrophy of the left ventricle; the impulse of the heart is more bounding, the apex beat is displaced lower and to the left, the percussion area is increased, but, above all, there is a sharp accentuation of the second aortic sound, plainly evident when the stethoscope is placed over the second costal cartilage to the right of the sternum. An important point in diagnosis is to distinguish the high pulse tension of Bright's disease from the hardening of arterio-sclerosis; in the former the artery is obliterated below the point of finger pressure, while in sclerosis it can still be felt in outline. With the sphygmograph a characteristic pulse tracing is given, and this means of diagnosis should be used whenever possible, for it gives evidence of high pressure which cannot be detected by the finger.

Other circulatory symptoms are dyspnœa, palpitation, reduplication of the systolic sound, and an uncomfortable pulsation in the head and other parts of the body; but with all these symptoms there is no heart murmur because there is no valvular disease, unless it be as a complication; in fact, cardiac hypertrophy without murmur usually means Bright's disease. The hypertrophy is a conservative process and may carry the patient along quite comfortably for many years; but when it finally fails we have dilatation and diminished blood pressure, and with it a diminished secretion of urine, high specific gravity, abundance of albumin and casts, cardiac dyspnœa, palpitation, dizziness, dropsy, and death from uræmia.

Dimness of vision due to albuminuric retinitis is a common symptom. It is often first recognized by the ophthalmologist, and generally means an advanced stage of the disease. Some assign two years as the limit of life after its recognition. Many cases of apoplexy show an interstitial nephritis at the autopsy. Dickinson[1] says that half the fatal cases of apoplexy are preceded by this disease.

It was not many years ago when albuminuria was synonymous with Bright's disease, and *per contra* the absence of albuminuria precluded Bright's disease. Both these conclusions we know now to be often erroneous, for on the one hand without Bright's disease we have the so-called "physiological or functional albuminuria," also the "cyclic albuminuria," and the "albuminuria of adolescence," all of which are conditions showing an intermittent or remittent albuminuria, usually in youths or young adults, especially after severe physical exercise, such as bicycle-riding or athletic sports. On the other hand, we know that in interstitial nephritis albumin is often, and in some cases constantly absent from the urine. An example of the functional variety of albuminuria recently came under my observation: A young man, aged thirty years, was spending his vacation in the East, and was indulging in much physical exercise, such as rowing, bicycle riding, etc. He met a friend there, who prevailed upon him to take out some life insurance while in New York. On examination, his urine showed a decided trace of albumin, and he was rejected. On his return home, after several days' rest, no albumin was found. Repeated examinations by myself and another physician have failed to show even a trace of albumin. Many insurance companies, however, now act upon the principle that physiological albuminuria does not exist, and that all these cases will sooner or later show an active nephritis. Millard[2] also says that physiological or normal albuminuria does not exist.

As an instance of the almost constant absence of albumin in a case of interstitial nephritis, I append the following history:

Mr. A. S. F——, aged sixty-five years, a hard-working, robust-looking farmer; no alcoholic history; began treating him two years ago. For five years he had had a most florid complexion with "bloodshot" eyes, and was often accused of drinking. He came for treatment for his "dizzy spells" and a flatulent dyspepsia. His appetite he said was too good; the bowels were constipated; his sleep was somewhat disturbed and he was compelled to arise once or twice each night to urinate. Physical examination showed great increase of arterial pressure with considerable arterio-sclerosis; his pulse was slow and very tense; hypertrophy of the left ventricle was evidenced by the displaced apex and accented second sound. The urinalysis at that time was as follows: Straw-colored, acid; specific gravity, 1.018; no albumin. For over two years repeated examinations failed to show even a trace of albumin, but the specific gravity has remained low and the daily amount of urine has ranged from sixty to eighty ounces. Recently, however, I examined a specimen passed after a brisk walk and found a good

trace of albumin, and after sedimentation two hyaline casts on one slide. His heart compensation is still good and there has been no dropsy or any severe uræmic symptoms. His urine for twenty-four hours recently gave the following findings: Amount, sixty-seven ounces; pale straw-color; acid reaction; specific gravity, 1.015; albumin, faint trace; urea, 1.60 per cent. or four hundred grains in twenty-four hours.

Tests for Albumin.—It is now generally conceded that there is no single positive test for albumin. The heat and nitric-acid test, if properly conducted, is the best, but it gives a reaction with mucin, or with a nucleo-proteid formerly mistaken for mucin. Symonds[1] advises the use of Heller's nitric-acid contact test to confirm the heat and acid test. Heller's test alone is hardly reliable, as the reaction does not appear for twenty or thirty minutes. Hare[2] says that this test is too fallacious to be used. Purdy[3] modifies the heat and nitric-acid test by first raising the specific gravity of the urine by the addition of a small quantity of a saturated filtered solution of common salt, and boiling the upper inch of the mixture in a test tube after slightly acidifying with acetic acid. He claims that this test possesses all the sensitiveness of the heat and acid test and avoids the mucin reaction, and that it is especially valuable when dealing with minute traces of albumin. I use this test often in suspected cases of interstitial nephritis in which the amount of albumin is unusually small. It is especially valuable in making a differential diagnosis between interstitial nephritis and the polyuria and low specific gravity of neurasthenia and hysteria, when the estimation of the twenty-four hours' urea is impossible. In any suspected case we should not exclude nephritis because we fail to find albumin. Measure the total quantity of urine in twenty-four hours and take the specific gravity of the mixed specimen. If the total amount is above sixty ounces, and if the specific gravity is below 1.018, our suspicions are well founded and the estimation of urea for twenty-four hours should be made and careful search for casts instituted; if interstitial nephritis exists, the amount of urea will be found below four hundred and fifty grains. The difficulty of finding casts is another source of error in the diagnosis of this disease. The condition is so chronic that the casts are few, and on account of the diluted condition of the urine, unless the sediment is obtained from a large quantity of urine—say two hundred and fifty to five hundred cubic centimetres—we may find no casts. Hence the method of Haines and Skinner[4] is very valuable; it consists of a combination of the subsidence and centrifuge methods. In obtaining a sediment for microscopical examination, about two hundred and fifty cubic centimetres or more of the urine is allowed to stand in a conical percolator for ten to eighteen hours, and then the lower stratum containing the sediment is placed in the centrifuge and subjected for two or three minutes to about three thousand revolutions a minute. The sediment is thus condensed to a small deposit at the apex of one or two tubes, consisting of one to four small drops, within which are practically all the casts of the large volume of urine employed. The casts found in interstitial nephritis are of the small hyaline variety and are not always easily seen, and require a fine adjustment of the light-regulating mechanism of the microscope.

Another difficulty in diagnosing this disease is due to the fact that the urine passed in the daytime only is examined instead of the mixed product of the twenty-four hours. Haig[5] has shown that during the day hours there is in this disease an excess of uric acid in the blood, producing contracted arterioles and high blood pressure, and in spite of the ingestion of large quantities of water the urine is scanty and of a fairly high specific gravity, but the blood is dilute, and when night comes the conditions are reversed. There is lessened uricacidæmia and the relaxed arterioles produce a great diuresis with a pale urine of low specific gravity, the night secretion being often twice as large as that in the daytime. Hence in all cases of nocturnal polyuria he advises a careful examination for other evidence of contracted kidney.

Determination of Urea.—Next to the recognition of the presence of casts in the urine comes the estimation of the daily excretion of urea. It does little good to know the daily amount of albumin escaping by the urine, for in some of the gravest forms of Bright's disease, *e.g.*, interstitial nephritis, the amount is very small; not so, however, with the urea. We know that the average healthy man between twenty and forty years of age excretes about five hundred grains of urea in twenty-four hours: in women and children the amount is somewhat less. In the several forms of Bright's disease this elimination may be reduced as much as fifty or even seventy-five per cent. We then have that variable train of symptoms known as uræmia. The regular estimation of urea excreted, therefore, is a most important part of the management of every case of Bright's disease, for by it we can tell the progress of the disease, the effect of our remedies, and often can even foretell a uræmic explosion with its convulsions, coma, and death. It is necessary in estimating the amount of urea excreted in twenty-four hours to test a sample of the mixed urine for that time. There are three methods in common use: the best consists in the use of the Doremus instrument. An alkaline hypobromite solution is used, which decomposes the urea in a definite amount of urine. A scale on the instrument shows the amount of urea.

With the reduction of urea there is noticed in this disease a considerable reduction of the phosphates. Purdy regards this as a diagnostic feature of the disease, and he has devised a quick method of estimating the phosphates by means of the centrifuge. The percentage tubes are filled to the 10 c.c. mark with the urine, and then an alkaline mixture of sulphate of magnesium is added until the 15 c.c. mark is reached. The tubes are then placed in the centrifuge and revolved at the rate of one thousand revolutions a minute for three minutes, when the bulk percentage may be read off from the scale; the bulk percentage in normal urine is about eight. With the percentage tubes I have used I have not found this method very successful, as the scales in the tapering ends are not perfect, and read differently when both tubes are filled with the same fluids for testing.

Unlike the other forms of nephritis, in a large number of cases of contracted kidney no cause is discoverable for the disease. Since it occurs mostly in adults, we cannot recognize any of the exanthemata as a causative agent; neither can we in many cases find a history of exposure to wet or cold. Dr. Clifford Allbutt has attributed twenty-four out of thirty-two cases in private practice to some long-continued anxiety or great grief. Tyson[1] does not believe that this cause often acts. Haig[2] has shown by most painstaking experiments the relationship of an excess of uric acid in the body and chronic Bright's disease. He believes all cases of interstitial nephritis to be only an ultimate result of uricacidæmia. He says he has seen so many cases of increased arterial tension due to uric acid, and cases of periodical sufferers from uric-acid headache or migraine finally eventuate into

[2] Haig: *Loc. cit.*

albuminuria and morbus Brightii, that he no longer questions the relationship. All investigators have noted the association of gout and contracted kidneys, and it is probable that all cases of chronic gout sooner or later show an interstitial nephritis. Uric acid in the blood is probably the cause of both conditions; and as an excess of uric acid in the blood is due to an excessive ingestion of meat and lack of exercise, we usually find these two diseases existing in persons who live well and consume a large amount of meat and take very little exercise. Chronic lead poisoning is regarded as another cause of interstitial nephritis.

Prognosis and Treatment.—We cannot cure interstitial nephritis, but if the patient will co-operate with us by proper dieting, mode of life, etc., we can promise him that his life may be prolonged many years and often indefinitely; let him remember that he must not eat anything that comes from a butcher's shop; let his meat be confined to fish and an occasional meal of poultry, but no eggs or other nitrogenous food; restrict the quantity of sugars and starches and encourage the ingestion of fats; he should drink an abundance of milk and avoid wines, spirits, and tobacco; exercise in the open air is very desirable, and an occasional change of scene and climate is beneficial; woollen undergarments should be worn throughout the year, the weight varying with the season; the night robe should be woollen and reach to the feet; plenty of water should be taken between meals and a moderate quantity at the meal; in all cases the bowels should be carefully regulated.

Many cases need no medicine whatever, but those patients who are apparently well, but with some hypertrophy of the left ventricle with a tense pulse, and who feel dizzy at times and have headache, are much relieved by potassium iodide, which softens the pulse and relieves the contracted arterioles. In treating this disease we must remember that there are two indications to be fulfilled: first, to remove an irritant poison from the system; and second, to relax the contracted blood-vessels. For the first object we give diuretics, such as acetate of potassium and digitalis; also diaphoretics, such as the hot bath or hot pack and pilocarpine, and then free catharsis. For the second purpose, that of relaxing the contracted arteries, iodide of potassium, chloral, and nitroglycerin.

Nitroglycerin is by far the best remedy for removing the symptoms due to high tension, such as dizziness, throbbing in the head, dyspnœa, etc. For the direct effect upon the pathological condition in the kidneys, most authorities believe in the long-continued use of small doses of iodide of potassium and bichloride of mercury.

Summary.—Interstitial nephritis is a very common disease, especially after forty years of age, and is often unrecognized for years. It is practically incurable, but life may be prolonged indefinitely in many instances by proper mode of life. A diagnosis must be made from a syndrome which often does not include either albuminuria or the detection of casts, as follows: (1) Polyuria with continued low specific gravity; (2) reduction in the daily excretion of urea; (3) hypertrophy of the heart (without valvular disease) and increased pulse tension; (4) various nervous symptoms, such as occipital headache, vertigo, dyspnœa, and insomnia.

The following symptoms or conditions, when found in any case, but especially in persons over forty years of age, demand a careful examination of the urine for evidence of interstitial nephritis: (1) nocturnal urination; (2) unaccountable weakness; (3) dyspepsia of a flatulent character, or a causeless diarrhœa, violent or spasmodic vomiting, or repeated "bilious attacks"; (4) dyspnœa, asthmatic attacks, or chronic bronchitis; (5) repeated headaches, especially if postcervical, persistent unexplained neuralgias, vertigo, insomnia; (6) bounding heart action or visible pulsations in various parts of the body; (7) severe hemorrhage from the nose or stomach; (8) dimness of vision, sudden blindness, or tinnitus aurium; (9) coma, convulsions, muscular twitchings, confused intellect, apoplexy.

SOME PNEUMOGASTRIC REFLEXES OF COMMON INTEREST TO PRACTITIONER AND SPECIALIST.

By J. WILKINSON JERVEY, M.D.,

CHARLESTON, S.C.,

SURGEON TO THROAT, NOSE, AND EAR DEPARTMENT, SHIRRAS' DISPENSARY; MEMBER OF THE MEDICAL SOCIETY OF SOUTH CAROLINA, AND OF THE SOUTH CAROLINA MEDICAL ASSOCIATION, ETC.

I AM well aware that in this paper I am touching upon a subject which has been worn to shreds, and even frequently exposed to ridicule by unreasonable and dogmatic individuals. That one poor, already overburdened little word "reflex" has been but too often called upon as the scapegoat for the physician who cannot otherwise account for existing signs and symptoms. To such an extent is this true that we often hear intelligent men damning the reflex and asserting that it is but a curiosity of etiology, and an unimportant one at that. Yet I am going to be foolish enough to observe that every symptom may reasonably be supposed to have a cause, whether patent or obscure; further, that the causes of many symptoms are frequently obscure; and still further, that many of the frequently obscure causes are responsible for symptoms produced by reflex nervous action and sensation. Moreover, while a reflex symptom is in no way symptomatic of its causation, still an abnormal condition of a given part can frequently be demonstrated to be the cause of symptoms more or less remote. So, too, we may have a symptom which could be caused by abnormal conditions in any one or more of a half-dozen different parts, so that the removal of a possibly causative abnormal condition of one part, without the cessation of the symptom, would not prove the absence of reflex. On the other hand, when a possible reflex cause has been located and removed, with the simultaneous disappearance of the symptom, there is but one reasonable conclusion to be drawn.

No one would be justified in removing or tampering with an organ apparently healthy, on the highly suppositious grounds of a reflex symptom; but when there is an affection of an organ which, time and again, has been demonstrated to be capable of producing the reflex symptom in question, there can be no reasonable doubt as to the indications for treatment.

No one can deny, with any show of reason, the frequent existence of reflex action and sensation in the human organism. The earnest wish in the minds of many men for the disappearance of these phenomena as phenomena is father to the thought expressed in a paragraph headline in the MEDICAL RECORD of May 21, 1898, "The Passing of the Reflex." The paragraph itself is a quotation from the pen of a neurologist, and winds up as follows: "In the mean time, under the keen scrutiny and rigid requirements of neurology, the so-called reflex as a cause of great nervous disorder is gradually being pushed into its rightful place—that is, among the relatively unimportant curiosities of etiology." Of course, the whole gist of this conclusion rests upon what is meant by "great nervous disorder." Nevertheless, the statement is misleading, for there can be no greater certainty than that "the passing of the reflex" will become a *fait accompli* only when the final passing of man has put the seal to all the ills that flesh is heir to.

It is my purpose in this paper to emphasize some of the commoner reflexes referable to the pneumogastric nerves and their connections.

A reflex is generally defined as an action due to reflected irritation, and not to volition; that is, it is an involuntary action produced instinctively by stimulation of a nerve centre. The afferent and efferent nerves of one locality are alone involved, as a rule.

There are, however, reflex sensations which cannot be considered analogous to reflex actions. By reflex sensation is meant sensation which may or may not stimulate action, and which is produced or influenced by irritation of a part more or less remote. That is to say, two or more parts having a common nerve centre or intercommunicating branches, irritation of one part may influence sensation or motion in a neuro-relative part—if I may be allowed to use the expression. Further than this, it may be asserted broadly that for an action or a sensation to be considered as a reflex, it must not be symptomatic of its cause; or, in other words, any action or sensation which is directly symptomatic of its causation is not a reflex.

A reflex sensation, then, is caused by an irritation in a given part transmitted to the nerve centre supplying that part; but tributary to the same nerve centre there is a network of nerve fibres from other parts, twining and intertwining, which must be passed through, many of them in direct communication with the message-bearing nerve. Is it to be wondered at that sometimes, even often, the message of irritation is taken up by these intimately connected fibres, and a stimulating alarm sent in as coming from the parts that they supply?

The recognition of reflexes forms part of the daily work of every general practitioner. The pain referred to the end of the penis in stone in the bladder; pain in the knee in morbus coxarius; pain diffused over the abdomen in appendicitis; pain in the shoulder and arm in cardiac disease; the vague pains of dysmenorrhœa, and others, are all under the almost daily notice of the family physician. But to the laryngologist, rhinologist, and otologist, reflex action and sensation are of especial interest and significance, for there is no field more fertile in these phenomena than the parts supplied by the pneumogastric nerve and its connections, whose terminal branches are within reach of external excitation and control in the ear, nasopharynx, pharynx, and larynx. The nasal fossæ and septum, too, are clinically deeply involved in pneumogastric reflexes, though their connection is rather more obscure. It is to be remembered, though, that their innervation is derived almost entirely from the fifth; and the pharyngeal branch of Meckel's ganglion arises close to, and sometimes together with, the Vidian, which supplies a considerable portion of the interior of the nose. Nor must we forget the connection between the fifth and tenth nerves, which will be shown farther on.

It is of paramount importance that these reflexes, or at least the most common ones, should be recognized by the general practitioner, and, if not positively diagnosed by him, their existence may at least be suspected and the specialist called in to account for signs and symptoms otherwise inexplicable. On the other hand, the dividing line between a direct and a reflex causation of a symptom is by no means easy of recognition; but in such a case the cause, whether direct or reflex, would probably be apparent, and there would be no difference in the treatment, this being directed to the cause regardless of the effects it has produced.

Macleod Yearsley, F.R.C.S., England, in an able and interesting paper in the May, 1898, *Journal of Laryngology, Rhinology, and Otology*, has emphasized the existence of "aural reflexes," pneumogastric and trigeminal. I shall refer only to the former, touching but lightly upon them, as upon the other pneumogastric reflexes, this paper being designed not for an exhaustive study, but only as a cursory exposition of conditions and effects, laying particular stress only upon the signs pointing to the existence of the commoner reflexes and the general methods for their control. Before going further, I shall call attention to a brief synopsis of the innervation accomplished by the vagus and some of its connections.

The external auditory meatus is supplied by branches of the auriculo-temporal branch of the third division of the trigeminus and by the auricular branch (Arnold's nerve) of the pneumogastric. The auriculo-temporal has branches of communication with the facial, and the branches to the external auditory meatus arise at the point of this communication; this is important, as the posterior auricular branch of the facial is joined in front of the mastoid process by a filament from the auricular branch of the pneumogastric. Thus the tenth nerve is both directly and indirectly involved in the nerve supply of the external meatus. The auricular, which is the first branch given off by the pneumogastric, is joined very near its origin by a filament from the petrous ganglion of the glosso-pharyngeal, which is the nerve of sensation to the pharynx, fauces, and tonsils. There exists, therefore, a direct as well as an indirect communication between the external auditory meatus and the pharynx.

The innervation of the middle ear is accomplished chiefly by branches from the facial and glosso-pharyngeal, both of which, it is to be remarked again, are in touch and connection with the pneumogastric.

In the pharynx a condition obtains much like that in the external auditory meatus. There is a special pharyngeal branch of the pneumogastric, and, through a communicating branch from the glosso-pharyngeal to the pneumogastric, the latter is indirectly as well as directly involved in pharyngeal innervation. And as we go farther down this pneumogastric area, we find each locality both directly and indirectly connected with its immediate neighbors, and each one ready, on slight provocation, to manifest its intimate nerve relation with every other part supplied by the great system of the tenth pair. Remembering now the extensive involvement of the pneumogastric in the external meatus, as already pointed out, and remembering that after the auricular the next branches of the vagus are, in order, the pharyngeal, superior and recurrent laryngeal, cervical and thoracic cardiac, anterior and posterior pulmonary, œsophageal, and gastric—it is not difficult to understand that sensory and motor disturbances could be and are often rapidly interchangeable among the organs suggested by this extensive nerve supply.

The first condition that I shall call attention to, and one of the commonest to be met with in the manifestations of the vagus reflex, is

Cough.—The reflex form of irritative cough may be associated with irritative excitation of the digestive organs. It is seen in varicose veins at the base of the tongue, in elongated uvula, and hypertrophied lingual or faucial tonsils. It is also seen in the pharyngitis sicca often found accompanying an atrophic rhinitis, though in this case it may be difficult to determine whether the cough is a reflex manifestation or a condition to be considered as directly symptomatic of pharyngeal disease. I have observed sometimes a persistent little dry cough in connection with adenoid hypertrophies of the nasopharynx, which disappears upon their removal. This is not a frequent condition, however, and is different from the slight cough combined with hawking and spitting often seen in adenoid hypertrophies, and caused by the dripping of the thick mucous secretion into the lower pharynx.

"Ear cough" is a common form of reflex. It is

usually of a small, dry, annoying, and persistent character. It is often caused by impacted cerumen, or foreign bodies in the external auditory meatus, and other abnormal aural conditions. The most limited experience in ear work would be sufficient for the recognition of this common condition. Yearsley says: "Such a cause for cough is not infrequently overlooked by the general practitioner, as in the following example: E. W——, aged sixty, paperhanger, complained of headache and troublesome dry cough. He was treated in the physicians' out-patient department of a general hospital for over a month, with various cough mixtures, etc. At the expiration of that time he began to notice a slight deafness, and came of his own accord to the ear department. Both ears contained plugs of hard, dry cerumen, which were removed by syringing, with the result that the cough disappeared in one day."

The treatment in ear cough, as in the other reflexes, is, of course, the removal of the cause. The MEDICAL RECORD of May 14, 1898, says that, according to Dr. P. Gastow in *Der Kinderarzt*, 1897, the common spastic night cough with vomiting and coryza in young children is usually of reflex origin. It is caused by the dripping backward into the pharynx of the mucus from a coryza posterior.

Another condition frequently met with in general practice is

Spasm of the Glottis or False Croup.—This is due in every case to reflex peripheral irritation. It may occur from the presence of irritating substances in the alimentary canal, or irritation caused by dentition. Frequently, however, it occurs from pressure on the superior or recurrent laryngeal nerve, caused by congested blood-vessels, enlarged glands or follicles, foreign bodies, or tumors. Ingals states that the attack is very likely to occur during an acute catarrhal inflammation of the larynx, and this view is borne out by other observers. As a further mark of its reflex causation, he says that with nursing babes it is frequently brought on by the entrance into the larynx of a little milk, and sometimes by dandling the child in the arms.

Spasm of the glottis may also be caused by irritation of Arnold's or Jacobson's nerve in the ear, transmitted to the fourth ventricle, and thence to the laryngeal nerves.

Lubet-Barbon, Paris, as cited by Ingals, says that adenoid hypertrophy in the nasopharynx is present in nearly every case of false croup. I have observed this in several instances, and I have further remarked the frequent presence of hypertrophied faucial tonsils. It would, of course, be palpably absurd, in view of the extensive area involved in the accepted causation of false croup, to assert or claim for one moment the invariable radical cure of the croupous tendency by the removal of "adenoids" or hypertrophied faucial tonsils. But it is not going too far to say that the removal of these conditions will lessen, and often markedly, this distressing tendency; and I do not hesitate to apply this knowledge, gained by my own experience, to the favorable influencing of a prognosis.

In the rational treatment of false croup, therefore, any possible cause should be located and remedied after an acute attack, with the view of preventing subsequent spasms.

Another common condition, and one which is frequently a veritable *bête noir*, is

Hay Fever or Rose Cold.—This is an affection not only attended with, but characterized by, reflex phenomena, the more important of which are sneezing and asthmatic attacks, referable to pneumogastric susceptibility. The asthmatic attacks may occasionally be due to obstruction of the nares, but this is unusual. The true cause of the reflex disturbances is a hyperæsthesia of the nasal mucous membrane. Usually there are to be found hypertrophies, exostoses, or other intranasal tumors. No treatment of hay fever can be successful without attention being given to local conditions in the nose. This alone can hardly be said to effect a cure, since the almost invariably present neurasthenic tendency and unfavorable atmospheric conditions must be taken into consideration. Still, I have seen eminently satisfactory results follow the control of localized hyperæsthesiæ, and the removal of spurs from the septum, or polyps, even when other indications for treatment were but imperfectly carried out.

Asthma is an affection very commonly induced by pneumogastric reflex action. I am not prepared to assert that all, or nearly all, cases of spasmodic asthma are due to morbid conditions of the upper respiratory tract. But there can be absolutely no disputing the statement that a very large percentage of these cases can be shown to be directly caused by such conditions. Ecchondroses or exostoses of the nasal septum, hypertrophied turbinated bodies, polyps, and other intranasal morbid conditions are frequently solely responsible for asthmatic attacks, and should be removed.

Of particular importance in this connection are adenoid enlargements in the nasopharynx, either a simple hypertrophy or a bursa-like formation (Tornwaldt's bursa), usually communicating with the pharynx by a sinus, and which may or may not contain a clear, fluid, viscid substance. I have had the most brilliant results in cases of spasmodic asthma by the simple removal of these conditions from the nasopharynx. Headache of a more or less severe type often, though by no means invariably, accompanies the asthmatic attacks, and is probably more often seen in connection with Tornwaldt's bursa, containing the fluid above referred to, than in simple adenoid hypertrophy.

Other tumors in the nasopharynx may cause similar symptoms, I take it. Irritating particles in the atmosphere lodging or striking upon the mucous membrane of the upper air passages may cause a reflex asthmatic attack.

Headache is one of the commonest of the vagus reflexes. It may be brought about by morbid conditions, chiefly in the ear, nose, and nasopharynx. Tornwaldt has reported several cases of nasopharyngeal catarrh with headache as a prominent symptom, which was relieved in each case by treatment directed to the nasopharynx. Bosworth says: "We must accept this interesting contribution to clinical medicine as confirming the teaching first made prominent by Hack, that in every case of cephalalgia a thorough inspection of the respiratory tract should be made in order to detect any possible source of irritation or diseased action in that region. Whereas the relief of this distressing symptom is one of the most creditable of our successes in throat practice, there is no special symptom in any given case of headache which warrants us in the positive assertion that it is dependent on disease of the air passages, and yet this distressing disease is relieved in a large proportion of cases by treatment directed to this region." This is important knowledge to the general practitioner.

Not long since a young lady, aged about twenty-eight, was referred to me by her family physician, a man of very wide experience and large practice. She had been suffering with persistent headache for months, and all treatment seemed useless. Her physician sent her to me with a request to examine her eyes for any refractive error that might be present. The eyes were absolutely normal, and from the nature of the case I determined to examine the nose and nasopharynx. She had told me that she was constantly annoyed by phlegm in her throat. I found a hypertrophy of the right inferior turbinated body and a chronic nasopharyngitis. I reported this to her physician, and in the absence of other causes ventured the opinion that

the headache was due to the conditions in the nose and nasopharynx. He smiled significantly and said he did not think so, but that I had better do what I could for the young lady. I did what I could, and she reported rapid improvement. I have not heard from her in some time, and so I presume the good effect has been lasting.

Another pointed case was that of a man, aged fifty-five, who was suffering from tinnitus aurium and headache. Posterior rhinoscopic examination revealed the presence of a small, round, hollow ulcer, about the size of a No. 4 shot, situated on the anterior cartilaginous rim of the left Eustachian orifice, and facing toward the posterior wall of the pharynx. I touched the ulcer with a thirty grains to the ounce silver-nitrate solution, obtaining almost immediate relief from the symptoms. This was a simple affection, yet a peculiar one, and I can find no account of any similar condition in any of the text-books.

Reflex headache may also be caused by impacted cerumen, foreign bodies, and other abnormal aural conditions.

Cardiac Reflexes are often met with where there is irritation over a portion of the pneumogastric area. A striking instance of this is as follows:

A young woman, aged twenty-four, was referred to me a few weeks ago, with the statement by her physician that she was in perfect health as far as his examinations could determine. Nevertheless, she was attacked almost daily with faintness, even to syncope, and much precordial distress. I removed a hypertrophy from the vault of the pharynx, with the result of marked improvement of the symptoms.

Faintness due to cardiac reflex is often caused by syringing out the external ear, by catheterization and inflation of the middle ear, and even by the introduction of a speculum into the external meatus. I have seen a big, healthy-looking man swoon away on the application of the curette to an aural polyp.

The Gastric Reflex is familiar to every one—tickling of the throat causing vomiting. Cases of nausea and vomiting from aural irritation have been recorded, and Mr. Yearsley has cited an interesting case, in his paper on aural reflexes, in which the gastric and cardiac reflexes were combined.

Epilepsy is said to be caused in not a few instances by abnormal conditions in the upper air passages. The well-known Marshall Hall considered the immediate cause of epilepsy to be spasm of the glottis combined with reflex spasm of the cervical muscles, resulting in venous engorgement and coma. Accepting this theory as true only in some cases, it can be readily understood that there could be an intimate relation between abnormal conditions of the upper respiratory tract and the causation of epilepsy. Personally I have never seen a positive illustration of this, yet from the number of authentic cases on record it would seem to be the duty of the attending physician to ascertain, and remedy if necessary, the existing conditions in the upper air passages of every epileptic.

Vertigo, Aphonia, Spasms of Pharynx and Œsophagus, and other pneumogastric reflexes have been observed, but are not so common; hence I shall not dwell upon them.

There are a large number of important nasal reflexes, other than pneumogastric; too many even to be mentioned in this paper. Bosworth devotes a chapter to them in his book on "Diseases of the Nose and Throat." Aside from this instance, I know of no text-book treating directly of reflexes. Other authors give only passing mention to some of the commoner ones, usually without remark or emphasis; yet it is plain to the simplest mind that they play an important part in practical, up-to-date, every-day medicine.

I have dealt only with the most common of the reflexes occurring in the regions supplied by the vagus and the ones which recommend themselves to the joint interest of the general practitioner and the specialist. I say joint interest, for it is generally necessary that the family physician should first recognize the existence of these conditions, preparatory to their falling into the hands of the specialist. There are, of course, many other and common reflexes which I have not mentioned, particularly of the eye, ear, and nose. Even to enumerate them would require entirely too much space at this time. Those that I have emphasized I particularly recommend to the hearty consideration and more general recognition of the medical faculty, not alone for the good of mankind, but for personal glory, for it often happens that more fame is to be gained by successful treatment of a persistent headache or an annoying cough than by the satisfactory conduct of a case of chronic Bright's disease or typhoid fever.

85 Broad Street.

LIGATURE OF THE LEFT SUBCLAVIAN IN THIRD PART FOR AXILLARY ANEURISM—RECOVERY—LIGATURE OF THE INNOMINATE FOR INNOMINATE ANEURISM—ALSO LEFT SUBCLAVIAN IN ITS FIRST PART FOR ANEURISM OF THIRD PART—RECOVERY.[1]

By T. E. SCHUMPERT, M.D.,

Surgeon to the Charity Hospital, Shreveport, La.

It is not my intention here to read a paper on the history of aneurism. I would not have the temerity to do that before a body of men who, like myself, have already had the privilege of listening to a most able and exhaustive paper on this subject by our most learned friend and confrère, Dr. Edmond Souchon, to whose paper I am indebted for some of the most valuable technique employed in my operations. My paper is drawn from a clinical aspect; is nothing more than the report of three cases of aneurism of the neck which I have operated on, with a few deviating steps from the hard-beaten path which I have dared to venture.

I will first report a case of ligature of the left subclavian in its third part for axillary aneurism. About three years since, there entered a patient in our hospital named Cas. A——, an American, forty-three years of age, complaining of a pulsating tumor, about the size of a hen's egg, under the left arm. He gave the history of having been shot in the back by his son with a shotgun loaded with No. 4 shot, while engaged in a difficulty with his wife. Five cicatrices marked the entrance of as many shot—two near the spine, one in the base of the neck, one in the scapula above its spine, and the other near the shoulder-joint. His wound was inflicted three months prior to his entrance in the hospital, and the suffering which the aneurism caused was very great. The function of the arm being entirely destroyed, I ligated the left subclavian in its third part. The wound healed kindly and the patient made an uneventful recovery. No pulse was perceptible in the left wrist for fifteen days. However, the temperature in the arm was at all times good and the pain and swelling rapidly subsided. The patient was discharged in good condition four weeks after the operation. I chanced to see him and his wife seven months later, when he informed me that he was entirely well and a much better man for his experience.

Ligature of the Innominate.—Caroline H——, a negress, aged forty-two years, was received in the

[1] Read before the Louisiana State Medical Society.

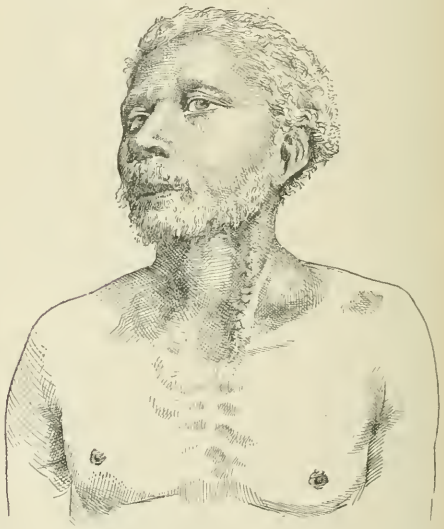
Shreveport Charity Hospital with a pulsating tumor, about the size of a large marble, behind the inner third of the clavicle. She complained of difficulty in breathing and a dull aching pain in that region. She gave no history of traumatism, nephritis, syphilis, or any of the acute infectious diseases; there was no redness or tenderness about the parts. These local symptoms together with the very audible bruit left no room for a mistake in the diagnosis of idiopathic aneurism, which was supposed to be of the common carotid near its origin. Her expression was languid, pulse only 60, and her general physical condition not good. My incision was begun on the sternum, two inches below its crest, and carried across the sterno-clavicular articulation parallel to but one-half an inch external to the inner border of the sterno-mastoid muscle, the entire incision measuring seven and one-fourth inches. The sternal attachment of the sterno-mastoid muscle was now divided close to the sternum, care being taken of the anterior jugular vein. The cervical fascia was exposed and divided in the line of the superficial wound. The common carotid was next exposed and traced to its origin. It was now that I discovered that I was contending with an aneurism of the innominate at its bifurcation and not of the common carotid, as I had supposed. The innominate was followed down to within a quarter of an inch of the aorta. The artery was cleaned and special care taken to avoid wounding the innominate vein, the vagus, and pleura. My needle, carrying No. 8 braided silk, was passed from within out and drawn sufficiently tight to control the circulation without severing the coats of the artery.

The wound healed primarily and the patient did well for four days, but she then began to show signs of coma, and died of cerebral anæmia on the ninth day. There was never discovered a pulse either in the right arm or in the temple, and it was interesting to note the difference in temperature of the corresponding sides during the first two days. The first forty-eight hours her pulse was 40 a minute and very feeble, but soon began to increase in volume and reached 68. By this time, however, her strength was too nearly expended for the reaction to sustain her. Had this latter condition existed from the first, I believe that a sufficient collateral circulation would have set up, the brain would have had its required amount of blood, and my patient would have recovered. Autopsy of the brain revealed a little softening and a slightly atrophied condition of the right side. I dissected the innominate artery and found my ligature encysted without the slightest irritation. Of one hundred and fifteen cases collected by Dr. Souchon in five there were cerebral symptoms; all were fatal.

Ligature of the Left Subclavian in its First Part for Aneurism of Third (Recovery).—Statistics do not offer much encouragement to one undertaking the radical cure of aneurism, by ligature either of the innominate or of the subclavian in its first part. Ligature of the innominate is much easier and not nearly so dangerous as that of the first part of the left subclavian, since the former is not so deeply situated nor so closely allied to vital structures. Ligature of the innominate has been undertaken in all twenty-one times, with one recovery. The right subclavian has been ligated in its first part fifteen times, with a similar result; the left subclavian has been ligated in its first part only twice, once by Dr. J. Kerney Rogers, of New York, whose patient died of secondary hemorrhage on the thirteenth day. The second case is my own, which I am now about to report.[1]

[1] It is true, however, that Dr. Halsted recently successfully ligated this vessel for the extirpation of a tumor. It was not ligated in continuity and the operation was altogether a different procedure with a different aim in view.

The operation for a long time was unanimously considered impracticable, and, until the day of Kerney Rogers, baffled the courage, ingenuity, and skill of the best operators as to some means of executing it, the situation of the artery being so deep and its relation with the most vital structures so intimate. Wyeth considers the operation of ligation of the first part of the left subclavian as the most formidable in the domain of operative surgery. Sir A. Cooper failed in an attempt to secure the vessel, and is said to have wounded the thoracic duct. Jacobson, in his "Surgery," writes: "It seems most doubtful whether the improvement in modern surgery will ever render this a successful operation; however, as it affords good practice on the dead subject, it will be given." Erichson considers the operation as bad in principle and most unfortunate in practice, and that it should be banished from surgical practice. Bryant says ligature of the subclavian in its first part on the left is scarcely practicable, and Mulley says the operation is quite out of the question. Treves believes that no artery could be less favorably placed for the application of a ligature, and in like



unencouraging manner treat all authorities writing on this subject. Yet in the face of these words of warning emanating from the brightest stars of the surgical world, when confronted with a malady so universally fatal we are prompted to summon courage and skill and attempt what has heretofore seemed an impossibility.

A negro by the name of James Hubbard, aged fifty-six years, was admitted to the Shreveport Charity Hospital with an aneurism, about the size of an orange, involving the third part of the left subclavian. The corresponding shoulder and arm were very œdematous and supported by the right hand. He complained of a constant great weight and aching of the parts; that he never had one moment of relief. He stated that about April 1st, while chopping a piece of timber overhead with a heavy axe, suddenly his arm gave way and the axe dropped by his side. After he had rubbed his arm for a moment its usefulness was restored and he proceeded with his work. Shortly after this a small pulsating tumor was noticed in the supraclavicular fossa, which obtained the size of an orange a month later (March 7th), when I operated in the presence of Drs. D. H. Billieu, Randall Hunt, and F. S. Furman, assisted by Dr. R. H. Gray and the hospital internes,

J. W. McGehee, D. J. Woolsworth, and J. D. McAnn. My incision was begun on the sternum, two inches below its crest, and carried across the sterno-clavicular articulation parallel to but one-half an inch external to the inner border of the sterno-mastoid muscle, the entire incision measuring seven and one-fourth inches. I then divided the sternal attachment of the sterno-cleido-mastoid muscle, and penetrated the deep fascia by blunt dissecting with flat curved scissors. I was now brought in contact with the internal jugular vein and actually denuded the carotid artery of its sheath two inches in an attempt to go between it and the vein, but at last was compelled to abandon this route and proceed by the tracheal side to the inner edge of the scalenus anticus muscle, half an inch above the first rib. My finger placed at the bottom of the wound first recognized the dorsal vertebra, then the artery, which was dissected clean, and an aneurism needle, carrying No. 8 braided silk, passed beneath it from the inner side. The pulse in the left arm was now taken note of and found to be of the same character as when the operation was begun, but when the ligature was tightened it ceased entirely. I was careful to see that no twist was in my ligature, that the side and not the edge lay in contact with the vessel, and that it was drawn only sufficiently to control entirely its circulation. A second ligature in like manner was placed about one-sixteenth of an inch above. The broad base of my first incision rapidly formed itself into a cone with a very narrow apex, which made ligature of this deep-seated artery extremely difficult. During the operation I found it necessary to use a long-bladed smooth retractor in order that it might be applied deeply in the wound and press away the jugular vein and aneurismal tumor, which was almost in contact with the trachea.

The divided segment of the sterno-mastoid muscle was brought together with catgut and the wound closed with catgut and dressed with iodoform collodion. Primary union subsequently followed under one dressing. It was not necessary to ligate a single bleeding point. My patient made an uneventful recovery, and is making himself generally useful about the hospital on this, the ninth week after operation.[1] The accompanying cut, from a photograph taken five weeks subsequent to operation, will show my line of incision; also the aneurismal tumor reduced two-thirds in size. You will observe that I have made my incision in a straight line and not angular, contrary to the advice of all text-books. The greatest danger of the preaseptic period was sepsis and secondary hemorrhage, the frequency of which drove many of the most skilled operators to abandon the operation; but with the advent of asepsis, the rapid healing of wounds, and the improved ligature, these dangers have vanished. I am sure straight incision and the preservation of muscle continuity favor primary union and therefore lessen the chances for septic infection, and offer a great advantage over the division of several muscles and an angular incision, as formerly prescribed. There is also an advantage in making the incision a little to the outer side of the inner border of the sterno-mastoid muscle, since by so doing we overcome the resistance of the skin in retracting outwardly and thus afford a wider field for operating. As Dr. Souchon in his deductions on aneurisms remarked, strict asepsis is the sheet anchor, and for that reason I do not take any undue credit to myself, but believe my success was because the day had come when the operation was to be performed by some surgeon. The reason why J. Kerney Rogers did not succeed was because he operated about fifty years too soon. While animal ligatures are rapidly growing in my favor, I must confess that on these occasions I was prejudiced in favor of silk.

[1] The œdema of his arm, shoulder, and hand has entirely disappeared, normal function being about restored, but no radial pulse is yet perceptible in the left arm.

OLIGOPHOSPHATURIA — A WELL-DEFINED AND IMPORTANT SYMPTOM IN DISEASE.

By GEORGE FREDERICK LAIDLAW, M.D.,
NEW YORK.

When Dr. Richard Bright entered upon the series of observations that has culminated in the worldwide recognition of the kidney lesions that bear his name, there was associated with him a man as enthusiastic in research and as accurate in his workmanship as was Bright himself. This man was Bostock. Bright studied the lesions in the kidney and established the general features of his proposition of the dependence of dropsy and albuminuria upon these renal changes. Bostock made chemical analyses of the urine and of the blood of the same cases, and supplied facts concerning the deranged urinary separation, without which much of Bright's proposition would have remained pure conjecture. All studies in the anatomy of renal disease which have been made since that time are based on the work of Bright. Our knowledge of the chemical properties of the blood and the urine in Bright's disease is based on the work of Bostock.

Bostock discovered that the urine of the patients under consideration was deficient in solids: he noted the deficiency both in urea and in the mineral salts. In the blood he found a substance resembling urea, and also an excess of the same salts that were deficient in the urine, and thus laid the foundation of our knowledge of uræmia. The presence of urea in the blood of nephritic cases was confirmed by Wilson in 1833,[1] and by Christison in 1839.[2] In this manner the substance urea took the lead in interest and apparent importance, to the neglect of its fellow urinary constituents, the inorganic salts. A review of the publications of the past twenty years shows that this attitude is still maintained by many competent authorities.

However, in our recent urological literature there are signs of an awakening. The inorganic salt is growing in importance, and the quantity of urea excreted is becoming less and less an element of certainty in prognosis. The growth of the idea has been slow. There was, first, in 1827, Bostock's observation[3] that in the newly discovered kidney disease the inorganic salts of the urine were present in much smaller quantity than in health. Next came Dickinson, in 1868,[4] with his careful quantitative analyses, revealing the fact that in chronic kidney disease there is a difference in the excretion of the different salts. In "granular degeneration" or interstitial nephritis, in amyloid kidney, and to a less extent in tubal or diffuse nephritis, he found that the excretion of phosphates in the urine during twenty-four hours was markedly deficient, the sulphates being less affected, and the chlorides usually appearing in normal quantity until late in the disease. There is another long interval until, in 1881, Fleischer[5] published his studies on the urine of nephritis. In speaking of chronic interstitial nephritis, he says: "The amount of urea excreted compared with that of the control person was sometimes very considerable; in other cases there was scarcely any decrease. . . . The excretion of chlorine was the same as in healthy persons. . . . Both absolute and relative excretion of sulphuric acid in one

case was lower; in another markedly less than in healthy persons. . . . The phosphoric acid excreted (in the form of phosphates) was in all cases, relatively and absolutely, decreased," as compared with a healthy person of the same sex and weight, and kept on the same diet. Fleischer discusses the reason for this peculiar inability of the chronically diseased kidney to excrete the phosphates, while the chlorides and sulphates pass freely into the urine: but he arrives at no profitable conclusion thereon.

In 1884, Purdy[1] is able to state that "he regards the diminution of phosphoric-acid excretion (in the form of phosphates) by the kidneys almost as constant a feature of the urine in Bright's disease and allied lesions of the kidneys as the presence of albumin in the urine." Again, speaking of chronic interstitial nephritis: "More or less reduction is to be noted of the quantity of all the urinary solids, the chlorides suffering the least reduction and the phosphates the most. With regard to the phosphates in particular, the diminution in the quantity of phosphates in the urine may be regarded almost as constant a feature of this disease as the presence of albumin."

Clifford Mitchell has confirmed this statement.[2]

I can not only confirm the statement of these observers, but will go a step further, and say that a deficient excretion of phosphates in the urine is the only constant urinary symptom of chronic nephritis with interstitial changes; it is more constant than albuminuria, more constant than low specific gravity or increased quantity of urine.

Bright himself, in 1836,[3] Christison in 1839,[4] Rayer in 1839,[5] and all observers since have noted the variability of albumin in the urine of the "granular kidney" or chronic interstitial nephritis. It is recognized by all that in this disease albumin may be very scanty, or may even disappear for long periods. Cases are recorded by Fleischer and Rosenstein, to which I can add six from my own observations, in which the excretion of urea, chlorides, and sulphates was practically normal; but neither I nor any other urologist has been able to record a case of chronic interstitial nephritis with a normal excretion of phosphates.

It appears, then, that in chronic interstitial nephritis and in waxy kidney there is a constant urinary symptom, namely, a diminished daily excretion of the salts of phosphoric acid. For convenience, in my clinical records and urological studies, I have called this symptom "oligophosphaturia," a self-explanatory term, analogous to "oliguria" and "oligocythæmia."

Constant urinary symptoms of chronic interstitial nephritis are not so numerous that we can afford to neglect any of them. It remains to consider how far this symptom, oligophosphaturia, is pathognomonic of chronic nephritis. Deficient daily excretion of phosphoric acid is not confined to nephritis; it is found in gout (Purdy) and chronic lead poisoning (Gaucher), some forms of anæmia (Deeke and Simon), in many acute fevers (Purdy and Simon), including the febrile stage of intermittent fever (Simon), during the intermission (Purdy), during pregnancy (Purdy), in acute yellow atrophy of the liver (Frerichs and Fleischer), and in cirrhosis of the liver (Hegar).

Note that most of these conditions are in some way related to deficient renal activity. Gout and lead poisoning frequently terminate in renal cirrhosis; anæmia tends to insufficient nutrition of the renal tissue, degeneration, and inefficiency; and the acute fevers, with their scanty, heavy urines and frequent albuminuria, point plainly to inadequate renal action. In my experience, the oligophosphaturia of pregnancy is a frequent but not an invariable occurrence. It is related distinctly to a greater or less degree of renal competence. The relation of oligophosphaturia to hepatic disease deserves more extended discussion than is possible in this article.

In a further communication, I hope to discuss the relation of this deficient excretion of phosphates to the "prealbuminuric stage of Bright's disease," described by Mahomed,[1] and the "diathèse Brightique" of Dieulafoy, and incidentally to demonstrate the value of the symptom in the early diagnosis of chronic nephritis.

The object of the present paper is simply to demonstrate to my fellow urologists the increasing importance that is being attached to the persistent deficiency of phosphates in the urine; to suggest a descriptive name, oligophosphaturia; and to urge the more frequent quantitative estimation of these salts by accurate analysis as an important element in every examination of urine. The estimation is easily and quickly made by the uranium-nitrate titration that is described in all standard text-books.

Progress of Medical Science.

The Treatment of Pott's Disease.—Dr. Périer (*Journal de Médecine de Paris*, No. 5, 1897) outlines the following treatment: 1. Upon the first manifestation of the disease the child should be put to bed, on a horsehair mattress, and kept in the horizontal posture. 2. It should, without change in posture, be kept as much as possible in the sunshine, either on land or water. 3. In winter the child receives before breakfast one-half to one tablespoonful of cod-liver oil, occasionally the syrup of tannic iodide. 4. Before each of the two chief meals the patient receives, during the first two weeks, from one to four drops of Fowler's solution; during the two succeeding weeks, a teaspoonful to a tablespoonful of the syrup of the iodide of iron. 5. Occasionally, instead of the above-mentioned drugs, the following mixture is given in one-half to one dessertspoonful doses:

℞ Sodii phosphat.,
Potassii phosphat. ..... āā 5
Syr. gentianæ 100
Vini Malagæ 500

6. The skin functions are to be improved and kept active by means of baths, massage, etc. 7. The diet is very important. Young children should receive meat, eggs, meat powders, and the like; if the digestion is good, and in older children, vegetables of all sorts should be given.

The Blood in General Paresis.—Dr. S. E. Jelliffe presents, in the *State Hospitals Bulletin*, vol. ii., Nos. 3, 4, 1897, the results of a study of the blood in twenty cases of general paresis. His results would seem to show that in this form of mental disease the blood-forming organs are certainly not primarily affected, and that they play but little part in the etiology or the course of the disease. The most striking and constant blood change consisted in a uniformly lowered hæmoglobin content, which would vary from fifty-two to ninety per cent. This was about the only constant factor observed. Many observers have noted in this disease a decrease in the number of red cells, but in these observations no such diminution was observed. The general conclusions expressed would seem to indicate that in general paresis there are no constant blood changes, that from a review of his own cases and those recorded in the literature of the subject there would seem to be a deficient formation in the lymphocytes, and that on a general average there is an increase in the large mononuclear leucocytes.

OPEN-AIR TREATMENT OF PHTHISIS.

THE opinions now held in regard to the treatment of tuberculosis are very different from those prevailing a generation or even a few years ago. Drugs were then generally regarded as the most formidable weapons with which to fight the disease, and the healing virtues of fresh air were almost totally ignored. However, as the study of bacteriology advanced, so also did the old-time views on the cause and treatment of consumption undergo a change, and Koch's discovery, that tuberculosis was produced by a microbe and was consequently contagious, gave the death blow to the existing remedial methods. On this side of the Atlantic the great benefit to be derived from pure air and suitable diet by those suffering from consumption has for a considerable time been fully recognized, and the treatment has been placed on a practical footing by the establishment of properly equipped sanatoria in various parts of the country. Some of the European countries, notably Germany, have followed our lead, while England has been the last to adopt the system, and, in fact, as yet has given it only a tentative trial. That in the United Kingdom the open-air treatment will be more widely followed in the future seems assured, as the movement to that effect is being warmly supported by many of the foremost English physicians. *The Practitioner* for June is devoted to a study of tuberculosis, and contains articles dealing with the disease from various points of view; but the writers of which are, one and all, agreed that climate, hygiene, and diet are the most powerful remedial agents. In the case of the wealthy these desiderata are naturally easily obtained, and the question of sanatoria affects this class to a comparatively slight extent; but for the poor or for those with but moderate means a sanatorium is almost a necessity. Until 1892 America was the only country which provided sanatoria for her poor, an example which has been since followed by Germany, Switzerland, France, Russia, Norway, and other countries. The results of treatment at these different sanatoria brings out one point in particular, namely, that the general methods of treatment are of greater importance than is the climate. Although an atmosphere free from moisture and with an abundance of sunshine, like that of Egypt, is the ideal one for a consumptive, yet most excellent results have been obtained from the open-air treatment in climates lacking these advantages. Dr. Léon Petit says: "In all the sanatoria, whatever their geographical position, the curative results obtained are nearly the same, provided that the hygienic method is applied there in all its scientific rigor. Here the climate may help the cure; . . . there it may hinder it. But it only exerts a secondary influence on the results of the treatment."

From the mass of evidence adduced since the introduction of sanatoria, it would appear that the methods of treatment pursued in those establishments have been most successful, and go far to prove that these methods are the only rational ones. As Professor von Leyden recently said: "The possibility of treatment outside a sanatorium with equally good results cannot be denied, but it requires much more prolonged rest and much more time on the part of the physician, and has by no means so certain a result. In any case I regard it as a great advantage if the patient can spend once or twice a period of several weeks or months in a good sanatorium."

THE SPECIALIST AND THE GENERAL PRACTITIONER.

AN old and familiar saying has it that no question is settled until it is settled rightly. Consequently if old questions keep coming up, it must be because they are still unsettled and the conditions of which they treat are still in an unsatisfactory condition. A forceful contribution to the discussion on the relations between the specialist and the general practitioner has been made in a recent number of the *Colorado Medical Journal* by Dr. Melville Black, of Denver. His thesis is that the general physician should receive a fee for referring cases to a specialist. We understand that his professional work is confined to a special line, and his views are presumably the result of his own experience. His main argument is thus stated:

"The general practitioner is called upon to render every kind of medical and surgical service. If he sees fit to send certain cases to a specialist, he displays a magnanimity unparalleled in other fields of labor. We will admit that in many instances his training and equipment are inadequate in some of the departments now presided over by specialists. The advancement of medicine and surgery has made it difficult for any one man to keep abreast of the entire field. He frequently recognizes that his knowledge in some one department is deficient, and being honest, he confesses his ignorance and sends the patient to a specialist. There are many instances where the practitioner has found it advisable to administer to his patient for several days before it is possible to refer him to a specialist. Again, in his anxiety for the welfare of his patient he may make several visits in the endeavor to cause the latter to consult the specialist, or may lose valuable time in going with him to the specialist. In any event he expends a certain amount of his time for which the patient will not compensate him. The patient and his family have long looked

upon him as their friend and medical adviser. They never think of paying him for aught except actual professional services. They would not consider such services professional, and he would gain their displeasure if he were to present his bill for the same. In case he has treated the patient for a few days, he would better erase any and all such charges for professional services from his books, because the patient considers that he has received no benefit from this treatment; that his physician did not understand his case or he would not have sent him to some one else. Therefore if this bill is presented no attention is paid to it, and if payment is pressed, the next time a physician is needed some one else is called in. Now who is to compensate this physician? There is but one answer—the specialist. If the specialist does not pay him for the time he has expended, no one else does. The specialist can easily learn from the patient the extent of the services rendered by his physician. The latter should then be compensated accordingly."

In those cases in which the opinion of the practitioner is asked as to the matter of consulting a specialist and one is recommended, no fee accrues, for the practitioner has rendered no definite medical service. His opinion has simply been asked as an adviser. He has not been compelled to spend his time on the case.

Dr. Black aptly says that many an obscure practitioner gains standing and even prominence through the specialist. Specialists to whom he refers cases make it a point to speak well of him whenever the opportunity is afforded. This is the only honorable way in which the specialist can return many favors and acts of kindness shown him by the general practitioner. On the other hand, many a specialist can either damn a practitioner with faint praise, or by some remark or even by some mannerism convey to the patient the fact that his treatment previously received at the hands of the practitioner has been far from right. That this is often done, no one who has had much experience with specialists will doubt. The trouble arises from the fact that the two medical men cannot always look at a given case from a common point of view. Here lies one evident danger of specialism—that of seeing a case only from the individual standpoint. "The specialist," says Dr. Holmes, "has only one fang with which to seize and hold his prey, but that is a sharp and cruel canine."

A practical difficulty in the arrangement of the scheme proposed is to find a basis on which an equable settlement could be made. Dr. Black does not recommend that physicians should be paid a stipulated percentage of all fees received from cases referred by them. Such an arrangement might lead to greater evils than those it aims to avoid.

In our view, much of the difficulty existing between the different classes of the profession at the present time is due to the fact that every man who reads the papers thinks that he knows at least half as much as the doctors. Between the various domestic remedies mentioned on the "only woman's page" of modern journalism, the semimedical lectures delivered in so many places, etc., the public has become demoralized, and the specialist has been placed in a position which he, if he be a right-minded man, is the last to claim. It would certainly do much to lessen the friction between him and his brother if there could be some well-understood principle of relative compensation which would be of universal application. In general, it may be said that most practitioners are on good terms with most specialists. Personal friendships do much to lessen the friction between those who are in a sense rivals, and it is a pity that those elements of character which underlie personal friendship cannot be broadly extended to all the relations of those who practise the healing art.

A DIPHTHERIA-ANTITOXIN DISCUSSION.

It is a strange fact that there still are some who reject *in toto* the antitoxin treatment of diphtheria. It is easy to understand that some might be dissatisfied with certain phases of the use of antitoxin and should seek modifications in its preparation and administration; but statistical evidence is so overwhelmingly in favor of the efficacy of this form of treatment that it is difficult to understand how it can be swept aside as inconclusive. In the *Berliner klinische Wochenschrift*, No. 27, 1898, Baginsky has taken the trouble to answer an objector to antitoxin treatment, in the person of Kassowitz, who had given his views at a meeting of a medical society in Vienna some time earlier in this year. He says that he cannot see how a fair mind could fail to be impressed by the reduction in mortality in any disease from about fifty per cent. to about ten per cent., and, having such figures presented, could fail to inquire into the cause of such a reduction. If such a change in mortality were simultaneous with the introduction of a new and radically different form of treatment, and if the same result were found in several series of cases and by various observers, a non-partisan judge could give only one decision, and that in favor of the new method of treatment. Many such series of cases from unimpeachable sources have been reported, and must be accepted as competent evidence.

Diphtheria is a disease of varied manifestations, and it affects different human organisms with different degrees of intensity. The specific organism varies also in the virulence of its action, and that action may be further modified by the simultaneous presence of other infective organisms. We know that the complications on the part of the heart, kidneys, and nerves are variable and uncertain both in their occurrence and in their course, and it would be unreasonable to expect identical results in all cases from any remedy. We cannot expect antitoxin to repair organic damage to the heart or kidneys, but we can expect it to prevent further damage to these organs, and this it certainly does, if clinical evidence is worth anything. If the remedy is not used soon enough, the damage to these organs may be so great as to be incompatible with life; but death under such circumstances should not discredit the antitoxin. Baginsky emphasizes again the fact that antitoxin from different sources varies greatly in its constitution and strength, and he rightly says that we must be sure of the quality of our thera-

peutic agent, that we must begin treatment early and consequently must make an early diagnosis, and that we must not neglect accessory means of treatment both general and local. It is true that several cases have been reported in which death has resulted very soon after the administration of antitoxin, but if such deaths are really due to something in the antitoxin, they only direct our attention more strongly to the necessity of care in the preparation and use of this agent. It is probable that the victims in these cases died from some cause depending upon changes in the nervous ganglia or in the kidneys, brought about by the action of the diphtheritic poison, and that the use of the antitoxin just before the onset of the unfavorable symptoms had only a temporal relation in respect of these symptoms.

YELLOW FEVER KEPT IN CHECK.

With the beginning of September we are reminded that this much-dreaded summer is nearly gone and the feared epidemic of yellow fever in the Southern States has not yet appeared. There have been sporadic cases at several places in the States bordering on the Gulf, but there has been no serious outbreak anywhere. The latest reports of cases of the disease have come from Key West and Galveston. The State boards of health in Texas, Louisiana, Mississippi, Alabama, and Florida have declared a quarantine against Key West, and some of them against Galveston as well. Encouraging news has, however, been received from both these places. At Key West no new cases have developed within the last three or four days, and it is believed that no fever exists there now. No new cases are reported at Galveston, and the quarantine established against the city has been raised, but it is continued against Fort Point, where the troops are quartered. To both the State boards of health and the Marine Hospital service we owe the fact that no epidemic has followed these sporadic outbreaks. Surgeon-General Wyman has shown that the Marine Hospital service is a most efficient sanitary organization, and one to whose keeping the health of the country may safely be intrusted.

Hospital Corps for Manila.—The following is the constitution of the hospital corps which has been assigned by General Miller to Manila: Major W. O. Owen will be chief surgeon and chief medical officer of the transport *Scandia*, which will carry the men from San Francisco. The others who have been selected are Lieut. Henry Page, assistant surgeon; Drs. Taylor Malaby, Ernest K. Johnstone, and Henry Phelan, assistant surgeons; Robert F. Gerahty, Frank K. Lar, Shelby G. Cox, hospital stewards; S. H. Cappelan, Frederick Gibke, D. S. Hutchins, E. E. Paterson, O. Rynning, Eugene Wood, acting hospital stewards; and one hundred and thirty-nine privates of the hospital corps. Several Red Cross nurses will also be taken. Colonel Stackpole, of the New York volunteers, will be in command of the *Scandia* when she sails, but the hospital corps will be under the command of Major Owen.

News of the Week.

Unappreciative of Medical Treatment.—The editor of the *Kansas Medical Journal* says that military surgeons get the same kind of treatment from their patients as the practitioners at home. In a letter recently published from one of the Kansas volunteer regiments, complaint was made that the sick did not receive proper attention and that for certain ailments they received two pieces of chalk, and the writer suggests that surgeons hereafter give to such complainants a taste of the crude drugs, and reserve tablets for those who appreciate the advances in therapeutics.

The Work of the Red Cross.—In a letter to the *Philadelphia Medical Journal* from Camp Cuba Libre in Florida, Maj. J. F. Clarke, of the army medical service, bears willing testimony to the invaluable services of the Red Cross Society at that place. "No one," he says, "should write from the front without giving great credit to the Red Cross Society for the great work it is doing. Without the aid of this society it would have been difficult to care for the sick in this hospital. Each day the Red Cross gives us fifty gallons of milk, two thousand pounds of ice, thirty dozens of eggs. Besides this it has built for us storehouses, floored our tents, given us hundreds of nightshirts, pajamas, pillows, sheets, buckets, bedpans, and dozens of other articles necessary for the care of the sick. In military channels the stream of supplies flows slowly and with many stops and much formality, but Dr. Kent, who represents the Red Cross here, gives freely and without delay. He has no regulation that prescribes how many bedpans one division must use, but gives all that are needed. This week, with the people of Jacksonville furnishing the motor power, he is going to put electric fans in all the tents."

Ice Cream and Typhoid Fever.—Coseley, some few miles from Birmingham, England, is at present going through an unpleasant experience of an epidemic of typhoid fever. Investigation has been made as to what this may be attributed to, and in at least five cases, *The Lancet* says, it has been traced to the consumption of ice cream. This is sufficient to show that the indulgences of an early age are not free from risks and that the opportunity for the gratification of such tastes requires to be attended with precaution in the manufacture of this much-sought-for dainty. Whether the authorities will be found equal to the occasion remains to be seen, though it is manifest that some intervention is strictly called for.

The Sanitation of Santiago.—The good effect of American methods is already evident at Santiago, where the number of deaths has fallen from an average of one hundred and three to one of thirty-seven a day since the occupation of the city by our troops. A board of inspectors has made a thorough examination of every house in the city, the streets have been cleaned, and the inhabitants are being slowly educated up to the point of looking upon filth as something undesirable and inconvenient. The yellow fever has been stamped out, at least temporarily.

A Curious Statute.—One of the sections of the law creating the Florida State board of health reads as follows: "Any person or persons who shall falsely or maliciously disseminate or spread rumors concerning the existence of any infectious or contagious disease shall be guilty of a misdemeanor, and, upon conviction thereof, shall be punished by a fine of not less than $100, or more than $1,000, or by imprisonment in the county jail for not less than three or more than six months." This is certainly an excellent way to make the outside world suspicious of the health of Florida.

The American Public Health Association will hold its annual meeting at Ottawa on September 27, 28, 29, and 30, 1898.

The Plague in Bombay is again prevailing extensively. During the week ending August 27th there were twenty-three hundred deaths from the disease in the Bombay presidency. The epidemic is spreading, and there has been a fresh outbreak in the State of Hyderabad. An interesting point regarding it is its increasing virulence—from 55.5 per cent. of fatal cases at the beginning to 89.8 per cent. a few weeks later.

The Marine Hospital Service in Hawaii.—Dr. W. D. Carmichael, at present in charge of the Cleveland Marine Hospital, has been appointed superintendent of the Marine Hospital service of the Hawaiian Islands. He will be stationed at Honolulu.

Illness of the Queen of Denmark.—A report from Copenhagen states that the Queen of Denmark is very seriously ill of kidney disease. She is suffering greatly from general anasarca.

A Woman Army Surgeon.—Dr. Anita Newcomb McGee has been appointed acting assistant surgeon in the United States army, and was regularly sworn in on August 29th. She has the rank and pay of a second lieutenant. Dr. McGee is a graduate of the medical department of Columbian University, Washington, in the class of 1892. Since the beginning of the war she has been in charge of the selection of the female nurses for the army.

Sickness in Porto Rico.—It is reported that fully ten per cent. of the troops in Porto Rico are suffering from malaria or typhoid fever, and all soldiers who can be spared from garrison duty will be sent back to the Northern States as soon as possible.

Spanish Opposition to the Red Cross.—A ship which sailed a few days ago from Santiago for Havana with a cargo of Red Cross supplies intended for the relief of the suffering of that city, reached Havana on Monday, and because Miss Clara Barton, who was in charge, had failed to provide a manifest of the cargo, the customs officers imposed a fine of $500 and forbade the landing of the supplies except on payment of heavy duties. Being no longer able, as at Caney, to shoot surgeons and others wearing the emblem of the Red Cross, the Spaniards in Cuba resort to these and other petty but exasperating actions expressive of their dislike for all who are inspired with humane motives.

Examination for Admission to the Marine Hospital Service.—A board of officers will be convened at Washington, Wednesday, November 9, 1898, for the purpose of examining candidates for admission to the grade of assistant surgeon in the United States Marine Hospital service. It is desired that applications for this examination be made before November 1st. Candidates must be between twenty-one and thirty years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to character. The following is the usual order of the examination: 1, physical; 2, written; 3, oral; 4, clinical. In addition to the physical examination candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate. The examinations are chiefly in writing, and begin with a short autobiography by the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. The clinical examination is conducted at a hospital, and, when practicable, candidates are required to perform surgical operations on the cadaver. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment the young officers are, as a rule, first assigned to duty at one of the large marine hospitals at Boston, New York, New Orleans, Chicago, or San Francisco. After five years' service assistant surgeons are entitled to examination for promotions to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, and surgeons $2,500 a year. When quarters are not provided, commutation at the rate of $30, $40, or $50 a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, ten per centum in addition to the regular salary for every five years' service, up to forty per centum after twenty years' service. The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. Further information may be obtained by addressing the supervising surgeon-general, United States Marine Hospital Service, Washington, D. C.

Recruits Wanted for the Hospital Corps.—There has recently been a great falling off in the number of applicants for positions in the hospital corps of the army, the impression being that since the cessation of hostilities there is no need for them. This, however, is a mistake. The demand is as great now as before. When the volunteers in the hospital service are discharged, the corps will not be more than half what is required. With a standing army of one hundred thousand men, a total of four thousand men for the hospital corps will be necessary. The recruits must be between eighteen and thirty-five years of age.

Sinking of a Hospital Ship.—The hospital ship *Olivette*, which was lying near the quarantine station at Fernandina, Fla., sank on Wednesday morning. Aboard of her were a hospital corps of thirty-five and a crew of forty-five persons, all of whom escaped without injury, and practically without clothes.

American Association of Obstetricians and Gynæcologists.—This association will hold its eleventh annual meeting in the banquet hall of the Monongahela House at Pittsburg, Pa., Tuesday, Wednesday, and Thursday, September 20, 21, and 22, 1898. The association will meet in executive session on Tuesday, September 20th, at 9:30 A.M., for the election of new fellows. The open session for the reading of papers will begin at ten o'clock. Recess for luncheon at 1 P.M. Afternoon session at three o'clock; recess at 5:30 P.M.; evening session at eight o'clock. The morning session will begin Wednesday at ten o'clock for the reading of scientific papers. Recess at one o'clock. Afternoon session at three o'clock. Adjournment at six o'clock. At 6:30 P.M., Wednesday, the executive session will convene for the election of officers, and for such other business as may come before it under the rules. The morning session will begin Thursday at 9:30 o'clock to continue until 1 P.M., when recess will be taken for luncheon. The afternoon session will be called at three o'clock and at five o'clock the closing ceremonies will be held. A full attendance is specially requested at the final session. At 8 P.M., Wednesday, immediately after the executive session, the annual dinner will be served at the Monongahela House. Thirty-two papers have been promised, and their titles are published in the preliminary programme recently issued. One of the sessions, or as much thereof as may be necessary, will be devoted to the presentation of pathological specimens and their histories, with discussion pertaining to the same. It is especially requested that photographs of these specimens be filed with the histories, from which engravings will be made for the transactions. Dr. Charles A. L. Reed, of Cincinnati, is the president, and Dr. William Warren Potter, of Buffalo, the secretary.

Foreigners at the Meeting of the British Medical Association.—There were sixty-four foreign guests and visitors registered at the Edinburgh meeting of the British Medical Association. Of this number fourteen were from the United States, five of them being from New York City.

The Library of the Late Dr. R. C. M. Page, of this city, has been presented by Mrs. Page to the University of Virginia. The library contains between six hundred and seven hundred volumes.

Prof. Rudolph Virchow has been made an associate of the Paris Academy of Sciences. He has been for many years a corresponding member.

The Prince of Wales' Hospital Fund.—The new stamps of the Prince of Wales' hospital fund will be issued during this month. The stamps, which bear a face value of 1s., 2s. 6d., 5s., and 10s. respectively, are each of different design and color.

The Mississippi Valley Medical Association.—The following is the preliminary programme for the meeting of this association at Nashville, October 11 to 14, 1898: B. Sherwood-Dunn, Boston, Mass., "Why I have Abandoned the General Practice of Vaginal Hysterectomy;" J. A. Stucky, Lexington, Ky., "Tonsillitis or Quinsy, Causes and Treatment;" H. W. Whitaker, Columbus, Ohio, "Pichi;" A. Ravogli, Cincinnati, Ohio, "A Few Practical Points in the Treatment of Posterior Urethritis;" Frank Parsons Norbury, Jacksonville, Ill., "The Neuro Hypothesis of Rheumatoid Arthritis;" A. M. Osness, Dayton, Ohio, "Diphtheria and its Logical Treatment;" F. E. Kelly, La Moille, Ill., "Varicocele:" F. F. Bryan, Georgetown, Ky., "A Plea for Pelvic Peritonitis and Cellulitis;" John M. Batten, Pittsburg, Pa., "Syphilis;" George W. Johnson, Dunning, Ill., "Gonangiectomy and Orchidectomy for Hypertrophied Prostate in Old Men;" George F. Keiper, Lafayette, Ind., "Wounds of the Lacrymal Apparatus, Report of Operation for Restoration of Canaliculi Obliterated by Traumatism:" Shelby C. Carson, Greensboro, Ala., "A Consideration of the Limit to Operative Gynæcology;" W. H. Humiston, Cleveland, Ohio, "The Relations of the Gynæcologist and the Neurologist;" W. Gaston McFadden, Shelbyville, Ind., "Intermingling and Changing of Type in Diseases;" William F. Barclay, Pittsburg, Pa., "Mercury and its Action:" J. Rilus Eastman, Indianapolis, Ind., "The Diagnosis of Gonorrhœa in Women;" S. E. Milliken, Dallas, Tex., "Subperiosteal Removal of Caries from the Pelvic Basin, with the Report of Cases;" Thomas Charles Martin, Cleveland, Ohio, "Complete Inspection of the Rectum by Means of Newer Mechanical Appliances;" George D. Kahlo, Indianapolis, Ind., "Hydrotherapy in Stomach Diseases;" Alex. C. Wiener, Chicago, Ill., "Surgical Treatment of Infantile Paralysis;" James M. M. Parrot, Kingston, N. C., "Suprapubic Cystotomy *versus* Perineal Section;" R. C. Pratt, McKenzie, Tenn., "Report of Cases in Obstetrics with Complications;" John L. Jelks, Memphis, Tenn., "The Relationship between the Genito-Urinary Tract and Rectum, with Special Reference to the Female;" T. Virgil Hubbard, Atlanta, Ga., "How Should We Treat Typhoid Fever?" W. W. Taylor, Memphis, Tenn., "A Clinical Contribution to Ectopic Gestation;" M. Goltman, Memphis, Tenn., "Interesting Surgical Cases;" I. N. Love, St. Louis, Mo., "The Bicycle from the Medical Standpoint;" Jos. Price, Philadelphia, Pa., "Surgical Treatment of Pus in the Pelvis;" Andrew Timberman, Columbus, Ohio, "Operations on the Mastoid, When and How Performed:" R. A. Bate, Louisville, Ky., "Arthritic Diathesis:" Charles W. Aitken, Flemmingsburg, Ky., "Diagnostic and Therapeutic Uses of Tuberculin;" G. W. Halley, Kansas City, Mo., "Some Pathological Conditions of the Ovaries and Adnexa Causing Pain."

Free Treatment of Deformed Children.—The Minnesota legislature appropriated last year a sum of $10,000 to provide for the treatment in hospital of all crippled and deformed children whose parents are too poor to pay for proper medical care at home.

Typhoid Fever at Camp Wikoff.—There are grave fears of an epidemic of typhoid fever in Camp Wikoff, at Montauk Point. There are many cases there now and it is believed that the water supply will surely become infected. Dr. Senn, who was sent there on his return from Porto Rico, is reported as saying that the camp will be a pest hole in a month or six weeks unless the troops are sent away. He said that the sanitary provisions throughout the camp and in the general hospital are inadequate to prevent the spread of typhoid fever, and that the soil at Montauk Point is of such a nature that nothing can prevent the contamination of the wells. In his opinion the establishment of the camp was a grave mistake. For similar reasons he had advised against the selection of the Chickamauga camp location, and he maintained that the soundness of his position had been proven by the event. Major Brown, the executive head of the general hospital, disputes Dr. Senn's statement of the conditions and his conclusions. He says that the sanitary arrangements at the hospital are such that the water cannot become infected with typhoid bacilli. The soiled clothes of the patients are disinfected before they are washed, and every possible precaution has been taken. Dr. Brown is quoted as saying that Montauk Point is a most suitable place for the camp. Surgeon-General Sternberg inspected the site before it was selected, and we believe that the events will justify his approval of the place and that Dr. Senn will prove to have been in this instance a false prophet.

Obituary Notes.—Dr. Ubald Laurier, brother of Sir Wilfrid Laurier, of Canada, died at Athabaskaville, Quebec, August 26th. He was well known in the United States, having practised for years in Chicago.—Dr. John L. Griffin, founder of East Los Angeles, Cal., and one of the pathfinders who took part as a government surgeon in the conquest of California, died recently. He was a graduate in medicine of the University of Pennsylvania in the class of 1837.—Major George McCreery, surgeon in the United States army, died on board the transport *Catania* at sea. He was born in New York, and was a graduate of Bellevue Hospital Medical College in 1877. He was appointed an assistant surgeon, February 17, 1880, and was promoted to the rank of captain, February 17, 1885. He attained the rank of major at the beginning of the present war. The body was buried at sea.—Dr. Owen J. Ward, of this city, died on August 17th, at the age of fifty-eight. He was graduated from the medical department of the University of the City of New York in 1865, and afterward served as house surgeon at St. Vincent's Hospital. He was visiting surgeon to Gouverneur Hospital.

The American Climatological Association held its fifteenth annual meeting at Maplewood, N. H., on Wednesday and Thursday of this week, under the presidency of Dr. E. O. Otis, of Boston. The subject of the president's address was "Avenbrugger and Laennec, the Discoverers of Auscultation and Percussion."

The Tuberculosis Congress.—The fourth congress for the study of tuberculosis was held in Paris, July 27th to August 3d, under the presidency of Professor Nocard, of Alfort. Many foreigners were present by invitation, among them Maragliano, Perroncito, Denys, Weichselbaum, and Bang. Eight or ten of the speakers related their experiences with Koch's tuberculin R, and were practically unanimous in condemning it, the sole point on which there was any disagreement being whether it did harm or not. Dr. Benoit, of Paris, was the only speaker at the congress who thought the discussion on the merits and demerits of tuberculin R should not be closed too hastily. The president, in his address, expressed a very positive opinion that tuberculosis is spread only by contagion, and that heredity is a negligible factor. Dr. Hirschfelder, of San Francisco, read a paper descriptive of oxytuberculin.

The Army and the Red Cross.—Surgeon-General Sternberg has published a statement regarding the attitude of the army medical department toward the Red Cross Society. In it he says: "It has been repeatedly charged in the newspapers that I am hostile to this organization and have refused to accept its assistance in the care of our sick and wounded soldiers, and that as a result of this refusal there has been unnecessary suffering. These charges are without foundation, except in so far as I have objected to the sending of female nurses with troops in the field engaged in active operations. We have a Red Cross hospital corps in the army of enlisted men, whose duty it is to render first aid to the wounded upon the field of battle and to care for the sick in our division field hospitals, and I have been of the opinion that female nurses would be an incumbrance to troops during active operations; but so soon as serious sicknesses developed in our camps and it became necessary to treat typhoid fever cases in our field hospitals, I gladly accepted the services of trained female nurses for the division field hospital, and in our general hospitals we have employed them from the first. The general testimony from the surgeons in charge of these hospitals has been that their services have been of great value. Very many of these trained nurses have been obtained through the kind assistance of the Red Cross Society for Maintenance of Trained Nurses, Auxiliary No. 3, and I desire to express my high appreciation of the valuable services rendered to the medical deparment of the army by this organiation."

Hospital on Fire Island.—The State of New York has offered to the war department the buildings on Fire Island for hospital purposes, and it is stated that about six hundred soldiers will be sent there as soon as the necessary changes can be made. The hotel and cottages belong to the State, and are leased with the proviso that they must be vacated at short notice when needed for health purposes. The men to be sent there will be from various States, no effort being made to reserve the island for the special accommodation of New York troops.

Reviews and Notices.

A Manual of Surgery for Students and Practitioners. By William Rose, M.B., B.Sc. Lond., F.R.C.S., Professor of Clinical Surgery in King's College, London, and Senior Surgeon to King's College Hospital, etc.; and Albert Carless, M.S. Lond., F.R.C.S., Senior Assistant Surgeon to King's College Hospital, and Teacher of Operative Surgery in King's College, London, etc. New York: William Wood and Company. 1898.

There is a decided dearth of concise text-books on surgery, both in this country and in Great Britain, suitable for the use of the ordinary student and adapted to the requirements of the general practitioner. Of excellent works on surgery there is no lack, but they are either too lengthy or too compressed. The work before us does not err in these respects; it is sufficiently comprehensive to meet the needs of a student preparing for the examinations in the United States and Great Britain—with the exception of those of the London University—and at the same time will serve as a valuable reference book for the man in general practice.

The first chapter, devoted to inflammation, deals with this difficult subject in a clear manner, and the importance of micro-organisms as a cause in the development of this disease is given the attention which it deserves. The chapter on suppuration and abscess is also good, the description and treatment of fistula being a model of the faculty of expressing one's meaning in a few sentences. The question of sepsis and infection is accorded a large space in the book and the latest views on the subject are plainly set forth. In the treatment of wounds the authors express opinions which will probably not meet with the approval of the majority of medical men in this country, for, while acknowledging that the aseptic method has been employed with much success, they avow themselves as strong upholders of the antiseptic mode of treatment. No exception, however, will be taken to their equally strongly expressed views as to the advisability of early massage in the treatment of fracture near joints; if this common-sense practice were more frequently followed, the stiffness so often complained of after injuries of this nature would be much less common. The chapter on abdominal surgery is very well written and is in line with the most modern surgical experience. Testimony is afforded in regard to the value of the Roentgen rays for the detection of penetrating foreign bodies of a metallic nature or of splinters of glass or stone, and the cryptoscope is well described. Owing to the need for compression and the consequent lack of space, historical and bibliographical references have to a large extent been omitted, while for the same reason diseases of special regions, such as the eye, ear, and female genital organs have been also practically excluded, except in so far as they encroach on the domains of general surgery. The proofs of the chapter on anæsthesia were revised by Dr. Silk, a sufficiently convincing evidence of the correctness of the views expressed therein. The book throughout is well printed and profusely illustrated, and should meet with a favorable reception. It should be mentioned that the less important diseases and conditions are printed in smaller type in order to economize space.

Wounds in War. The Mechanism of their Production and their Treatment. By Surg.-Col. W. F. Stevenson (Army Medical Staff), A.B., M.B., M.Ch., Dublin University; Professor of Military Surgery, Army Medical School, Netley. New York: William Wood and Company. 1898.

As Professor Stevenson truly remarks in the preface to the above work, probably no branch of surgery has undergone more important changes, in consequence of the teachings of Lister and of Pasteur, than that of gunshot wounds. Surgery in the field, which was more or less the practice at the time of the civil and the Crimean wars, is distinctly prohibited by the requirements of modern treatment. Probing for bullets is a thing of the past; in fact, the modern bullets, with their envelopes of steel or cupro-nickel, render the Nélaton probe useless, as they do not stain the porcelain tip as did the old leaden bullets. Hospitalism is also almost unknown. Thanks to the improvement made in the structure and management of the buildings devoted to the treatment of wounded soldiers, to the efficient ambulance service, and especially to the adoption of Lister's teaching, limbs which but a few years ago would have been promptly amputated are now saved as a matter of course. Penetrating gunshot wounds of the skull, chest, and abdomen, which in the majority of cases were looked upon as fatal, are now treated with fair chances of success. The progress in the science and art of surgery made during the past twenty-five years has been phenomenal, and has created an urgent need of a systematic and up-to-date English treatise on military surgery. The works of Longmore, Guthrie, McCormac, and Macleod were excellent in their day, but in view of the changed conditions of modern warfare have outlived their usefulness. The same must be said of G. A. Otis' monumental "Surgical History of the War of the Rebellion." Professor Stevenson is well equipped for the task of compiling a work dealing with the wounds in war under the altered conditions, as besides being an instructor at the Army Hospital at Netley, he has himself had a wide experience in actual warfare. The first chapter details at length the construction of modern weapons and missiles, compares the curves of their trajectories, and the dynamics of the flight of their bullets. The characteristics of the injuries produced is fully entered into, and the conclusion arrived at is that with the ordinary small-calibre rifle bullets the injuries are much less severe than those caused by the old Snyder and Martini-Henry rifles; and it is pointed out that medical officers—who served in the Waziristan and Chitral expeditions of 1895, where Lee-Metford rifles were first used in warfare, state that the English small bore cannot be depended on to stop a man in his charge. In the chapter on the treatment of wounds in war, special stress is laid on the necessity of "first field dressing" and the danger of interfering with wounds at "the front" is strongly insisted upon. As a striking illustration of the rapid progress which is being made in the science of military surgery, it may be noticed that, although Professor Stevenson's book was published in 1897, the use of the Roentgen rays is not referred to. It is since the publication of the work—in the Afridi campaign in India, at the battle of Atbara in the Soudan, and in our recent fight before Santiago—that the practical value of this means of locating bullets was clearly demonstrated. With regard to the treatment of injuries to joints and bones, attention is drawn to the growing tendency of the army surgeon of the day to the pursuance of conservative methods. That part of the treatise referring to penetrating wounds of the skull, chest, and abdomen is excellently written, and exhibits in a conclusive manner the marvellous revolution effected in military surgery through the agency of aseptic teaching. The surgery of the face, ear, and eye is omitted, as scarcely coming within the scope of a work of this size. The last chapter in the book, on the Geneva Convention and the duties of the Red Cross Society, is, considering the prejudice that appears to exist among surgeons, both in our army and the British army, against that body, in a high degree interesting. Professor Stevenson must be congratulated on having produced the best work on army surgery under modern conditions that has as yet been published.

Manual of Physical Diagnosis. For the Use of Students and Physicians. By James Tyson, M.D., Professor of Clinical Medicine in the University of Pennsylvania, and Physician to the University Hospital; Physician to the Philadelphia Hospital. Third Edition. Philadelphia: P. Blakiston, Son & Co. 1898.

This new edition of Dr. Tyson's well-known manual is an improvement over the preceding, in that new matter has been added to bring the book thoroughly up to date, additional illustrations have been introduced, and some of the sections have been revised. The young physician and the advanced student of medicine will find in this little book an all-sufficient guide to the diagnosis of most organic diseases, with the important exception that there is no section on urinalysis, this subject having been treated by the same author in another work.

Medical Diagnosis. A Manual of Clinical Methods. By J. J. Graham Brown, M.D., F.R.C.P.E., F.R.S. Ed., Assistant Physician to the Royal Infirmary, Edinburgh; Lecturer on the Principles and Practice of Medicine in the School of Medicine of the Royal Colleges, Edinburgh. Fourth Edition. Philadelphia: P. Blakiston, Son & Co. 1898.

Although this is called the fourth edition, so long a time has elapsed since the third edition was exhausted that it may be regarded as practically a new work. So rapid are the advances in certain methods of diagnosis, especially as regards

examination of the blood, urine, and stomach contents, that a work of this kind is in need of constant revision in order to maintain its position as a trustworthy guide, and to such revision Dr. Brown has manifestly submitted his book, for the latest methods, at least such of them as have been proved by the touchstone of practical experience, are here described briefly but sufficiently. After a somewhat careful examination of the manual we are confident that no young man who trusts himself to its guidance can go far astray.

A System of Medicine. By Many Writers. Edited by Thomas Clifford Allbutt, M.A., M.D., LL.D., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge, Fellow of Gonville and Caius College. Vol. VI. New York: The Macmillan Company. 1898.

The sixth volume of Dr. Allbutt's excellent "System" is devoted to diseases of the respiratory and circulatory systems, with the exception of diseases of the arteries, a consideration of which has been deferred to the next volume. The editor has himself written four of the articles, and several of the other contributions are from the pens of well-known English authorities. The subjects are such as will interest every practitioner of medicine, for the diseases are among those most frequently encountered in a general practice, and most of them are handled in an instructive and pleasing way.

The Blood. How to Examine and Diagnose its Diseases. By Alfred C. Coles, M.D., B.Sc. of Public Health, Edinburgh, etc. With Six Colored Plates. London: J. and A. Churchill. 1898.

This is a useful guide to the diagnosis and pathology of morbid changes in the blood, either primary (so-called) or secondary to general diseases. After a preliminary chapter on methods of examination and general morphology of the blood, the author takes up the primary anæmias, including chlorosis, pernicious anæmia, leucocythæmia, and Hodgkin's disease. Under the heading of secondary or symptomatic anæmia Dr. Coles treats of the condition of the blood in malignant disease, malaria, the acute and chronic infectious diseases and dyscrasiæ, and various general diseases, such as myxœdema, gout, and diabetes.

Exiled for Lèse Majesté. By James T. Whittaker. Cincinnati: Curts & Jennings. 1898.

This book was, as the author tells us, composed in fulfilment of a promise to his family to write a story for their entertainment during the Christmas holidays. The story is a slight one, with just enough love-making to keep up the reader's interest while he is imbibing a vast amount of knowledge on all conceivable subjects with which the cultured man or woman must be more or less familiar. Dr. Whittaker betrays the physician in several places where his characters touch in their *causeries* upon medical subjects; yet this is perhaps not strictly true, for he equally betrays the literary man, the bookworm, the astronomer, the geologist, and the political economist. The book is replete, indeed, with most useful information, and we cannot now recall one since "Sandford and Merton" which the young could read with greater intellectual profit. And the older ones may also find entertainment and instruction in its pages.

Tropical Diseases. A Manual of the Diseases of Warm Climates. By Patrick Manson, M.D., LL.D. Aberd., F.R.C.P. Illustrated by 88 Wood Engravings and 2 Colored Plates. New York: William Wood and Company. 1898.

Only a few years ago it was a common reproach to British medicine that, despite the immense tropical possessions of Great Britain, there was scarcely anything of value on the pathology of the tropics written by physicians educated in the United Kingdom, Fayrer having been almost alone in the cultivation of this prolific field. Now, however, there has been an awakening, and with the establishment of a journal of tropical diseases, the founding of a school in London for the teaching of tropical pathology, and the creation of a section of tropical diseases in the British Medical Association, we may look for great advances in this branch of medicine. And no small contribution to this advance is the work of Dr. Manson, whose industry and acumen have already raised him to the highest rank among the investigators in this line. The work appears at a most opportune time for American physicians, many of whom, especially the young ones, will doubtless be led to cast in their lot with our brethren dwelling in our just-acquired tropical possessions. Dr. Manson speaks as one with authority, and rightly, if a personal experience with nearly every disease of which he treats can confer such a right. We welcome this excellent work, which may confidently be recommended as a safe guide to a theoretical knowlege of the obscure diseases with which it deals.

Clinical Department.

HYPEROSTEOMA OF THE DURA; INFRADURAL FIBROMA; JACKSONIAN EPILEPSY; APOPLEXY; DEATH; NECROPSY.[1]

By HENRY WALDO COE, M.D.,
PORTLAND, ORE.,
AND
E. D. JOHNSON, M.D.,
PORTLAND, ORE.

While osseous tumors are usually found in connection with the normal bone, the case here reported is another evidence that such is not always the case. A new bone formation, if spread out, is denominated by Ziegler as a hyperostosis; if confined to a limited area, as an osteophyte; and if of considerable size, as an exostosis. Tumors of the dura are rare, usually small, and are scattered over or through the membrane, being disconnected osteomata. The present case may be fairly classed as a hyperosteoma of the dura, there being an osteoma of large size.

A case such as this excites inquiry concerning the etiology and the pathology of such growths. Certain writers have claimed and sought to establish the theory that these tumors are prone to occur in those who inherit or develop large bony frames. In the present case the man was of rather a large size, but nothing abnormal in his osseous system was noted outside of the cranial cavity. Gowers tells us that in pachymeningitis externa, when pus has not been formed, there remains a thickening of the outer layer of the dura mater, firmly connecting it with the skull, and into this tissue osteophytic growths may extend from the skull.

Fig. 1.

There is no history of a pachymeningitis, nor does the specimen which is shown in the illustrations indi-

[1] Read before the Oregon State Medical Society, June 2, 1898.

cate that there has ever been an inflammation of the dura. The bony deposit is not, as in the osteophytic examples, found in separate nodular growths, corresponding to areas of adhesive inflammation; the bony deposit is quite general over the hemisphere, the secondary deposits being immaterial in size and to be accounted for by the peculiarity of situations in which they are found. No special adhesions were noted in the post-mortem examination, and the dura was opened with as great freedom as though the peculiar condition found had not existed, there being no evidence of any meningeal inflammation present or past.

Calcification is not an uncommon process of degeneration. An aggravated case of this, wherein a large portion of the apex of the heart had prior to death calcified, was presented before the Portland Medical Society by Dr. Charles H. Wheeler a few weeks ago. The micro-photographs reproduced herewith demon-

Fig. 2.—Longitudinal Section.

Fig. 3.—Transverse Section.

strate that this deposit is not an interstitial calcification, but real bone structure, probably developed from the cellular embryonic tissue existing between the two layers of the dura, this development having been instituted in fœtal life. In such a case, as pointed out by Ziegler, there must have appeared in such development between the formative cells a homogeneous or fibrillated dense basement substance, which gave a resting-place for calcareous salts, the osteoid trabeculæ being an early element in the construction of this particular dura.

Within the dura and closely attached to the inner layer of that membrane, may be seen a small tumor. It is clearly a fibroma. In size it is about two by one and a half inches, and a half inch in thickness.

A feature of interest in the larger bony specimen is the depressions showing where Pacchionian bodies had nested in the new bone formation, giving the whole an appearance of the interior of a normal skull cap.

The history of the case is as follows:

H. J. B——, aged forty-three years, was admitted to the Oregon State Insane Asylum, January, 1894. The commitment papers stated that he had had epilepsy when a child and again when he was fourteen years old, from which he appeared to have recovered; he had no more attacks until he was thirty-three years old, since which time they had grown frequent and severe, causing mental weakness and partial paralysis of the right side. No description of the character of the attacks was given. When admitted he was quite strong and well nourished, and could give a fairly good account of himself, though he was unreliable in his statements, partly from loss of memory. The epileptic attacks were distinctly Jacksonian, the spasm involving the hand and face first, then extending to the whole right side of the body. They were of irregular occurrence, frequently being absent for several weeks, while other times they would occur as often as one every minute for several consecutive days. The seizures varied in intensity from a slight tremor to a tonic convulsion, and the patient usually retained consciousness. Motion on the right side of the body was considerably impaired when he was admitted; it improved gradually for a time, but was never completely restored. In May, 1897, he was suddenly stricken with complete paralysis of the right side, evidently from cerebral effusion, but after a few weeks the paralysis gradually improved until he was able to walk with a cane, although the arm improved but very little. The convulsions were almost entirely absent for several months after the paralysis developed. About two months before he died slight spasms in the right hand and forearm began to occur, which gradually increased, becoming very frequent, almost continuous, and tonic in character, and two days before he died involving the whole right side.

Upon post-mortem examination the head had a normal appearance and was symmetrical in shape. Nothing abnormal about the body was discovered, except within the cranium. The calvarium was of average normal thickness, and, as before stated, there were no inflammatory adhesions between the skull and dura. There was no fluid in the subdural or arachnoid spaces. Upon the removal of the skull cap almost the entire left hemisphere was found to be covered by a bony sheet within the layers of the dura. A smaller portion of ossification was found over the central region of the right side. Within the bony tumor and closely adhering to the inner coat of the dura was found the tumor before referred to. This growth lay over the motor tract of the left side of the brain. The lateral ventricles were distended with serum and blood clots, death being the result of this hemorrhage.

TWO CASES OF CARCINOMA SUCCESSFULLY TREATED BY THE ELECTRO-MERCURIC METHOD.[1]

By G. BETTON MASSEY, M.D.,

PHILADELPHIA.

Mrs. B——, aged sixty-three, had the right breast removed for carcinoma of a malignant type in January, 1897. Ten months later she came under my notice with seven carcinomatous nodules which had developed in the course of a lymphatic vessel, which extended from the scar of the operation upward toward the clavicle. These growths were of the size of hazelnuts, were in the subdermic tissues, and were rapidly increasing in size.

On the 11th of December, 1897, she was placed under ether with the assistance of her physician, Dr. Ida E. Richardson, and of Dr. Willard Thompson, and the cataphoric method was applied by means of three small gold electrodes amalgamated with mercury, the electrodes being so inserted as to include all seven of the growths in their field of influence. Before the current was turned on an excess of metallic mercury was injected through the electrodes, in order that an abundance of this metal would be in the proper situation for cataphoric dissemination throughout the growths. The current was now turned on without shock, the active electrodes being positive and a large pad on the back negative. Before the full current employed—five hundred milliamperes—had been turned on, there was evidence of change at the point of insertion of the instruments, and by the expiration of fifteen minutes all of the growths had

[1] Read before the Philadelphia County Medical Society, May 11, 1898.

been softened and an area beyond them infiltrated and changed to a grayish color. The operation was complete at the end of fifteen minutes, when the current was turned off and the patient put to bed.

Considerable pain followed the application in this case, lasting four hours, but it ceased at the end of this time and the patient was thereafter comfortable.

The spot was dressed with a dry powder and remained in an aseptic condition until the débris came away, some two weeks later, after which it healed by granulation. No further treatment was required, and the patient is now well, with no evidence of unsound tissue anywhere. The axilla remained uninfected in this case, both at the time of the removal of the breast and when she came under my notice.

The second case to be reported this evening was an instance of carcinoma of the sublingual salivary gland on the left side of the tongue in a woman, fifty-six years of age, who had noticed the lump for six months, during which time it had grown rapidly. For two months it had caused her excruciating pain, day and night, and she had been latterly quite unable to take nourishment. On examination the lump was found to be of the size of a horse chestnut, with an ulceration occupying its centre, which emitted a horrible odor, so strong indeed as to affect the air of the whole house when she was admitted to the private hospital.

On the 28th of December last she was etherized, and the electro-mercuric method applied with the assistance of Dr. S. J. Gittelson. A large gold electrode, well insulated to near the tip, was thrust into the centre of the growth and four hundred milliamperes were turned on, an abundance of mercury being injected about the tip of the instrument. As the current was not very strong, the application was prolonged to thirty minutes. The indurated base and surroundings of the tumor seemed softened by this time.

During the passage of the current it was noticed that the odor had ceased, and it never returned, though grayish shreds remained in the situation of the growth until thrown off by nature about two weeks later. The intense pain from which this patient suffered was also found to have ceased by the next day, and it never recurred. A slight additional application was made to a portion of the growth that had escaped the original treatment, about three weeks later. The bared area gradually healed by granulation, and I have the pleasure of exhibiting the patient to-night in a state of perfect health.

The diagnosis of the first case was corroborated by a microscopic examination when the breast was removed. In the case of the patient exhibited this was accidentally omitted, as the small piece removed by me for this purpose was mislaid by the microscopist and lost during an attack of illness. The clinical features of this case were nevertheless so pronounced as to leave no doubt of its malignant character.

MATERNAL IMPRESSIONS.

By EDWARD D. ELRIGHT, M.D.,

MARION, KAN.

I HAVE in my practice a case of maternal impression, so marked that I wish briefly to report it. In visiting a house in my capacity as physician I noticed a little girl, about six years of age, with a remarkable-shaped head and a blepharo-phimosis of the right eye. The forehead was very prominent, running to a sharp point a little to the left of the centre. The entire right side of the head was but poorly developed, being not nearly so full as the left side. I operated on the eye, enlarging the palpebral opening. I still had left a ptosis. I then removed a strip of the lid and found entire absence of muscular tissue. The ball was turned decidedly upward. With regard to the cause, which is the interesting part, I learned the following: The mother when about two months pregnant saw her husband, who is a butcher, killing a cow. He had hit it on the head with an axe, crushing in the right side and causing the upturned eye to protrude. She hurried away, but the sight made a deep impression on her. Cause and effect seem to be certainly connected in this case.

ENLARGED PROSTATE AND SPINA BIFIDA IN THE NEGRO.

By T. M. McINTOSH, M.D.,

THOMASVILLE, GA.

DR. W. L. RODMAN, in a paper read at the meeting of the Kentucky State Medical Society, "Influence of Age, Sex, and Race, in Surgical Diseases," speaks of the great rarity of enlarged prostate and spina bifida in the negro race. The following cases may therefore be of some interest. I was called ten miles south of this place to see a negro man, about sixty-five years old, who had had retention of urine, a high fever, and repeated chills for two days. In unsuccessful attempts to introduce a catheter before I saw him, an injury had been inflicted upon the urethra. I employed an ordinary gum-elastic catheter with stylet, No. 10 English scale, properly curved, and with a finger in the rectum it was easy to pass the instrument into the bladder and draw the urine.

A negro woman, living seven miles east, was delivered of a dead child, with a spina bifida as large as the child's head. In the suburbs of the town I saw recently a negro child, a few days old, with a spina bifida as large as a cocoanut. The child died in a few days.

SOME HINTS ON THE MANAGEMENT OF SIMPLE SPASMODIC CROUP.

By JOHN H. BILLINGS, M.D.,

NEW YORK.

THE importance of examining the nasopharynx in so-called cases of spasmodic croup occurring in children can hardly be overestimated.

It was my fortune to have under observation the past winter six cases of the ordinary spasmodic croup, coming on at night, yielding, however, to the ordinary simple remedies. On examination of the nasopharynx the following day, three cases presented enlarged tonsils and nasopharyngeal adenoids, three the nasopharyngeal adenoids simply.

These six cases were treated surgically—that is, the tonsils were excised and the adenoids removed; and, although this took place early in the winter, no attacks were experienced again in any of the six patients, these children being called "croupy" and suffering since birth from frequent attacks during cold weather.

In all cases of this character it seems that an examination of the fauces might lead to the exciting cause, in the great majority the obstruction to proper nasal breathing rendering the child catarrhal and croupy, and predisposed to attacks of this nature.

It might here be well to call attention to the importance of keeping the room quiet and the child's attendants calm and collected, the exhibition of excitement and fear on their part causing the little patients to struggle and the attacks of stridor to be greatly intensified. I have often been able to carry the croupy child through the night without the least difficulty, by simply having the room quiet and the attendants cheerful, carefully avoiding any expression of fear in words or manner.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-Sixth Annual Meeting, Held in Edinburgh, July 26, 27, 28, and 29, 1898.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 321.*)

SECTION ON SURGERY.

Second Day—Thursday, July 28th.

The Origin, Effects, and Treatment of Septic Infection of the Urinary Tract.—DR. DAVID NEWMAN, of Glasgow, opened a discussion on this subject. He proposed to confine his attention principally to changes taking place in the kidneys, leaving other speakers to deal with the rest of the tract. In the first place, there were certain conditions, not necessarily septic, but often leading to suppuration. He would, however, limit his remarks to truly septic conditions. He would classify these as follows: Purulent embolic nephritis, a descending sepsis without pre-existing disease of the tract; purulent interstitial nephritis, ascending by the lymphatics; acute septic nephritis without suppuration, ascending by the lymphatics to the cortex; suppurative pyelitis affecting the mucous membrane of the pelvis without distention; the same without secondary infection. The mucous membranes of various parts of the body have the power of protecting it against micro-organisms and of destroying them; the bladder is no exception in this respect. Simple retention of urine did not cause sepsis. The artificial introduction of organisms would not cause it unless the mucosa were damaged or there were retention. The kidney was protected by its situation and by the peculiar arrangement of its lymphatic supply, which had hardly any communication with the lymphatics of neighboring parts. It was isolated, too, by its fibrous capsule, and was situated outside the peritoneum. The interrupted valve-like action of the ureter prevented spread of sepsis as long as it was not dilated, and the frequent emptying of the bladder also helped to protect it. If any of these conditions were interfered with, sepsis might occur. The commonest cause was a central or local nervous lesion. The modes of attack were the following: (1) Infarctions causing purulent embolic nephritis; (2) by the lymphatics; (3) by the excretory duct; (4) by continuity with other organs; (5) by wound. Under the first head came endocarditis, erysipelas, osteomyelitis, etc. These usually gave rise to wedge-shaped emboli and numerous abscesses, which might rupture into the pelvis of the kidney or cause secondary infection of the local blood supply. If the submucosa of the ureter were injected, the fluid would travel up to the cortex of the kidney and travel down into the pelvis. The whole structure of the kidney was surrounded by lymphatics, which also were continuous with those of the submucosa of the bladder. Acute sepsis and suppression of urine might occur directly after operation, especially in those who had large white kidney. Death occurred in a short time, before suppuration could develop, but in these cases micro-organisms were found in swarms everywhere. In cortical abscess infection took place along the lumen of the excretory ducts. Here were found chronic nephritis, dilatation of the ureters, and direct infection reaching to the uriniferous tubules and extending to the lymphatics, and so spreading farther. In chronic hydronephrosis infection might occur by migration of organisms from the alimentary tract. A similar process occurred in cystitis. All instruments were ordinarily septic, and even after sterilization the instrument might become septic before it reached the bladder. Even after the introduction of microbes a good deal might be done to mitigate their effects and destroy them.

DR. THORKILD ROVSING, of Copenhagen, referred to his book on this subject. The results and opinions there detailed he had arrived at from personal treatment and the bacteriological examination of about two hundred cases. A great number of microbes might cause diseases of the urinary tract, but there were two chief groups—those which decomposed urea and those which were known under the name of coli bacilli. He had shown that infection might descend from the kidney, and, much more frequently than was supposed, it was conveyed through the blood. Sterilization of instruments did not prevent cystitis, because the normal urethrea swarmed with microbes. Infection through the blood had its source generally in the intestines and through the kidneys. Guyon and his school taught that almost all infectious diseases of the urinary tract were due to bacterium coli, while the urea-decomposing microbes were of secondary importance. In bacteriuria or epithelial cystitis the urine contained no abnormality except bacteria, and it was turbid and sometimes had a peculiar odor. There was no frequency of micturition and the cystoscope showed the mucous membrane to be normal. With the urea-decomposing non-pyogenic microbes (staphylococci, diplococcci, rod bacteria) there was ammoniacal turbid urine with pus-like deposit. Micturition was frequent and painful; the cystoscope showed the mucous membrane red and swollen. This he had described as catarrhal cystitis. Pyogenic microbes caused a suppurative cystitis, if they for a time only were able to render the urine ammoniacal. For the production of pyelitis when the bladder was healthy coli bacteria were responsible; when it also was affected, we had almost always to do with urea-decomposing pyogenic microbes. The following experiments, Dr. Rovsing said, were instructive: Tie one of the ureters of two rabbits and inject coli bacteria into one and staphylococcus aureus or proteus Hauser into the other above the ligatures. The second rabbit will be dead in a day or two with diffuse suppurative nephritis. The other will be alive. If the rabbit is killed after two, three, or even eight or nine days, the urine will swarm with coli bacilli but there will be no suppuration of the kidney. The greatest number of urinary infections per urethram were caused by surgical interference; therefore prevention of infection by this means was important. Vaseline should not be used as a lubricant. He had found a bladder half full of vaseline. Sterilized olive oil or glycerin should be used. Oil was the best. It was, however, most necessary to kill the microbes introduced by instrumentation. The only preparation to be relied on was a two-per-cent. solution of nitrate of silver, of which forty or fifty cubic centimetres should be introduced and retained three or four minutes, after which the bladder should be washed out with sterilized water.

MR. MANSELL MOULLIN thought that the septic origin of urinary troubles was overlooked through the habit of treating these organs as not subject to the same general laws as the rest of the body. Urine was provided to be aseptic in health. The bladder was particularly liable to attack by micro-organisms through the blood or neighboring organs. Experiments had shown that organisms injected into the rectum might appear in the bladder, and the frequency of cystitis after rectal operations was well known. Similarly the colon might infect the kidney. Pyelitis occurred in pregnancy, due to the pressure of the uterus on the ureter, but this disappeared when the pressure was removed. Doubtless the most common mode of infection was by the lumen of the tract.

Infection was easy in women, owing to the shortness of the urethra and its proximity to the vulva. Infection was easily got rid of also for the first reason. In one method of infection the blood or lymphatics were primarily affected, in the other the urine. Bacteriuria without cystitis passed gradually into cystitis when the vitality of the bladder wall was lowered. Organisms would account for all the extraordinary symptoms in urinary sepsis, except those due to shock. At the beginning of catheter life, when there were cystitis and residual urine, death sometimes occurred, and was put down to exhaustion or to typhoid symptoms, but really it was due to sepsis. The way to prevent this was to empty the bladder thoroughly and not to let the organisms get in. Personally the speaker had found bacillus coli present in most cases. The virulence of this organism varied enormously; some were almost innocent, while others were very pathogenic. He could not agree with Dr. Rovsing as to the innocence of bacterium coli. If it could cause pyelitis, as he admitted, why should it not cause cystitis? Bacterium coli was often found in almost pure culture, and he thought in such cases it was fair to infer that it was the cause.

Dr. Melchior, of Copenhagen, said that in bacteriuria the urine was acid, with a bad smell, and contained crystals of uric acid and oxalates and leucocytes. He gave statistics of his cases. The bacterium coli was the most frequent organism in cases of cystitis; it was found in half, and was introduced from without by instruments. In five cases of spontaneous cystitis he found it in pure culture. The urine was acid and there was no pyelitis. All the five cases occurred in women; he had never known such in men. It was due to the anatomical arrangement of the parts. The bacillus coli was found on the vulva and even in the healthy female urethra. Even with urea-decomposing microbes the urine might remain acid in cystitis. He narrated an interesting case of disappearance of the coli bacillus and appearance of others, with change of character of the cystitis. The different suppurative conditions, such as cystitis, urethritis, and pyelitis, were not separate entities, but ran into one another. Diseases of the intestinal tract affected the bladder and urinary tract. He held that pyelitis with cystitis, caused by the bacterium coli, was a descending affection, the cystitis being secondary; this was contrary to what Rovsing taught. Bacterium coli then was the commonest cause of these diseases, and with it the urine was acid. It might also be acid when the urea-decomposing microbes were predominant.

Mr. Bruce Clark emphasized the etiological importance of abrasions of the mucosa and of retention of urine; it was proved that injection of microbes might be harmless when neither of these conditions was present. This was shown by catheterization, which, although continually performed without any antiseptic precautions, did not generally cause infection. He agreed with Rovsing that cases of streptococcus and staphlyococcus were commoner than was generally thought. It often occurred that a case first showed staphylococci and then bacterium coli. He believed that, as Klein suggested, the latter was the hardier bacillus and drove out the first. Here possibly was an explanation of some of the conflicting statements of different observers. Streptococci might invade the submucous tissues of the bladder and render it incapable of expansion, as in erysipelas of the skin, etc. If streptococci were found in the urine in cystitis, he thought that operation was indicated in order to keep the bladder quite empty, so as to get at its walls and treat them directly. Any method of disinfection of catheters must be simple, because patients must use it themselves.

Mr. Battle related a case of perineal section for urethral calculus with purulent pyelitis and greatly enlarged kidneys. After lateral cystotomy and drainage the patient recovered entirely and the kidneys returned to normal size: a very rare result.

Dr. Nicoll said that the common mode of infection was per urethram. He had undertaken a series of observations with the help of bacteriologists. He was not yet prepared to state results, but they had made clear that there were many sources of fallacy and the subject was a most difficult one, and as yet they had arrived at no fixed conclusions. Cultures must be made on acid, alkaline, and neutral media in all cases before a verdict could be given in testing the sterility of the urethra. There was no known method by which the gonococcus could be distinguished from other cocci. Microphotographs had to be taken of all slides, because the earlier specimens stained by Gram's method might be found decolorized when wanted later for comparison. He was quite prepared to find that further investigation upset the conclusions provisionally come to.

Dr. MacEwan, of Dundee, said that the practice of passing the catheter on females without exposure was to be condemned severely. It was impossible to keep an instrument sterile when used thus. Infection from within was difficult to deal with, but purges and internal antispetics were useful before operations. Catheter fever was due to sepsis. Organisms were absorbed by the abraded urethra on the first act of micturition after use of an instrument. As antiseptics, methylene blue, and salol by the mouth, and boric acid, nitrate of silver, and perchloride of mercury locally were the best. A suprapubic opening was the best for inspection and drainage of the bladder.

Dr. Kocher, of Berne, said that in several cases of peritonitis he had found nearly pure cultures of coli bacilli. If this bacillus killed others in cultures it might do so in the body, and it might even be benign and its presence in an abscess, for instance, a good sign. If Rovsing's views were all true, it might be beneficial to inject coli bacilli in cases of cystitis from other organisms.

Dr. Newman, in reply, said that he was in some doubt as to the importance of the coli bacillus. No doubt it varied in virulence. There were great contradictions in practice. He had a patient who had been using a bougie, improvised out of eighteen inches of telegraph wire, for years without much harm, yet a single application of Holt's dilator killed him in forty-eight hours. It exposed, no doubt, a large absorbing surface.

Thyroidectomy in Graves' Disease.—Dr. Stokes, of Dublin, read a paper on this subject. A case which he reported was that of a man of thirty-two years, which began after a fright. There were typical symptoms of Graves' disease. Von Graefe's sign, however, was not well marked. There was no osteomalacia. There was some temporary improvement under ergot and thyroid extract. Thyroidectomy was performed successfully despite somewhat alarming attacks of dyspnœa. The patient entirely recovered. Three views were held of its etiology: (1) that affection of the heart was the primary cause; (2) that it was caused by disturbances in the central nervous system; (3) that it was caused by absorption of toxins secreted by the thyroid. This last had most adherents. Thymus-gland treatment was useless. The results of thyroidectomy pointed to this gland being the cause of symptoms. Seventy-four patients were cured, forty-five were improved, and only three were not benefited. Shock appeared to be the starting-point in many cases. (1) Enlargement of the gland was the first symptom in some; (2) palpitation and exophthal-

mos in others. There were a complete and an incomplete form. We should distinguish in treatment between cases beginning with tachycardia and those beginning with enlargement. No treatment but operation was curative. Total extirpation was not always necessary.

The President referred to the alarming symptoms which appeared under anæsthesia in such cases.

Dr. Kocher said that the result of these operations was most gratifying, but not in all cases, because perhaps for fear of myxœdema not enough was removed. He excised one lobe and one-half or two-thirds of the other, and tied three out of four arteries. Chloroform was most dangerous in such cases. He gave no general anæsthetic but operated with cocaine, and if the patient would not consent to this, he refused to operate at all, except in children. It could easily be done with cocaine, and patients were astonished at the slight pain they suffered. Perhaps, although the gland accounted for many of the symptoms, it did not account for all. The central nervous system might be the cause. But he was perfectly sure that surgery could cure a good many of these cases.

Cleft Palate.—Mr. Edmund Owen reported a case of cleft palate. The child should be got into a good state of health. Adenoids or large tonsils should be removed previously. He used Smith's gag with spikes instead of roughened plates, and kept the head hanging back. Incisions laterally should be very free indeed. If a case went wrong from infection by staphylococci, one must wait and do a secodnary operation when the edges were granulating.

Electrolysis of Inoperable Malignant Tumors.—Dr. Melchior, of Copenhagen, read a paper with this title. He had had good results in some cases, the tumor disappearing, with no return after two years. He applied a current of five hundred milliamperes for five minutes. Both electrodes were introduced into the tumor, avoiding large blood-vessels. It had a far-reaching effect beyond the actual tumor and necrosis took place in the new growth only. The current seemed to possess a valuable quality of discrimination. It affected sound tissue by causing reaction with some pain and development of fibrous tissue, which helped to choke cancerous cells. Others besides himself had made observations under the microscope of the discriminating effect of the current. He had applied as much as six hundred and eighty milliamperes without bad effect. The method was not dangerous unless such a current were passed through the brain substance. The development of fibrous tissue might have bad results, but the patients were in a desperate condition and should be told that the method was uncertain and dangerous.

Chloroform Anæsthesia in India.—Dr. Arthur Neve, of Cashmere, read a paper on "Chloroform in India—A Plea for More Utilization of Clinical Facts." He had addressed inquiries to many practitioners in India. In five principal hospitals there were 15,800 administrations with two deaths in the past year. In a longer period there had been 78,400 administrations with only three deaths. Surgeons responsible for over 100,000 administrations had not had a single death. The patients were of many races—Europeans, Mongols, Pathans, Dravidians, and Aryans. The diet varied greatly. The operating-threatres were very freely ventilated. Anæsthesia was produced more easily in warm than in cold weather. Sir Benjamin Richardson had stated that cold and especially moisture were prejudicial or even dangerous. To this Clover agreed. It was worthy of note that the two deaths in India last year occurred at two very moist places. Dosage was not secured by Junker's or the modified Junker's inhaler. He poured measured quantities on a towel. Last year in Cashmere thirty pounds were used in seven hundred administrations, an average of five and one-half drachms in each case. Laurie averaged seven drachms. On the average two and one-half drachms were used in twenty minutes; about half of this was inhaled and still the strength of the vapor was probably one per cent. The evidence in favor of occasional fatal neuroparalysis was, he thought, overwhelming. He thought we should assimilate the conditions of administration in this country to those in India, in order to attain corresponding safety. The section decided to ask the association to memorialize the government of India to publish a yearly report of the statistics of administration of chloroform in India.

Catheterization of the Ureters.—Dr. David Newman read a paper on the value of this procedure. He was sorry to say that in those cases in which it most was wanted, catheterization of the ureters was not feasible. There was danger of spreading infection from the bladder to the kidney. It was valuable in deciding the condition of the kidneys before deciding to operate. He would use this means only in cases in which it was absolutely necessary and as a last resource. He could not admit that washing out the pelvis of the kidney through a minute catheter was of any use. It must be incised and drained.

Dr. Leopold Casper showed his instrument for catheterization of the ureters. In the use of it infection was possible, but practically there was no danger. He had used it for practice and diagnosis five hundred times and had never known infection to follow. The urine washed back into the bladder any organism introduced into the ureter, but yet precautions should be very thorough. He would use it only when necessary for diagnostic or therapeutic purposes. It was of value in cases of tumor when there was doubt whether the urinary apparatus was affected or not. In one case echinococcus of the liver was diagnosed, but the general practitioner suspected kidney disease because the tumor varied in size. His instrument proved it to be a case of pyelo-nephritis. Diagnosis in some cases could be arrived at by the cystoscope, but not so early or so surely. Its main usefulness was in determining the condition of the supposed healthy kidney when an operation on the other one was proposed. Urine could be obtained for analysis.

Spina Bifida.—Mr. Yelverton Pearson reported a case of spina bifida treated by open operation. The tumor was in the loin. The patient had lordosis, contraction of ham strings, and nocturnal incontinence of urine. The operator made a lateral longitudinal incision, the patient lying on one side, removed an elliptical portion of the skin and sac, turned up flaps of dura mater, and attempted to form periosteal flaps. He undermined the skin at each side and made free incisions through the aponeurosis, so as to enable the latter to be sutured on the midline. Result good. There was temporary palsy. This and the incontinence passed away. The knees were treated with splints. The child had generally much improved.

Third Day—Friday, July 29th.

Hemorrhage of the Kidney.—Dr. Thorkild Rovsing, of Copenhagen, read a paper on "Mysterious Hemorrhage from a Single Kidney and its Cure by Nephrotomy." *Hæmaturia sine materia*, essential or genuine hæmaturia, was much talked of early in this century. Rayer devoted a chapter to it. Later surgeons, operating for hæmaturia and finding no cause, began to discuss the subject anew. Klemperer had called it hæmaturia from a healthy kidney and supposed it due to a neurosis. The speaker believed that those cases reported were most doubtful. He had had four cases under his care, of which he read full notes.

In two the kidney was displaced, and the urine infected with bacterium coli. Free exploration of the kidney was followed by complete cure. In both cases the kidney was replaced and fixed in its normal position. He believed the hæmaturia was due to displacement and torsion, giving rise to venous stasis, although possibly the coli bacteria had something to do with it, as he had described several cases of bacteriuria beginning with a single hæmaturia.

In another case the kidney was severely pressed between the liver and the ribs by the stays, and in its upper part its substance was too friable to hold a suture.

In the remaining case he could find no cause for the bleeding, but it was not certain that it was not from a vessel in the pelvis of the kidney or in the ureter. Nephrotomy appeared to cure the condition, as in the other cases. This should always be resorted to in these cases.

The President remarked that mysterious forms of hæmaturia were rapidly disappearing under improved methods of diagnosis.

Neurectomy in the Treatment of Spasmodic Wryneck.—Dr. R. H. Parry reported a case of spasmodic torticollis treated by neurotomy of the cervical plexus. A workman, aged thirty-seven, seen in 1895. Three years before that he had received a severe blow on the neck. This was followed by pain and soon his mate noticed his head jerking. Five months after the injury he had to leave off work because his head was so far drawn toward the left shoulder that he could not look at his work. Neurotomy of the right spinal accessory did no good. The platysma and sterno-mastoid on the right side and the left occipital muscles were in constant clonic spasm during the day; there was no jerking during sleep, but the head then remained turned to the left. There was no structural shortening of the muscles.

Stretching under an anæsthetic, massage, etc., were tried in vain. An operation was therefore undertaken. An incision was made along the posterior border of the left sterno-mastoid. The great occipital nerve was found and divided, as was the posterior division of the first nerve; those of the third and fourth were difficult to find, but were at length divided. The occipital artery and vein were ligatured. The wound was packed with gauze; it healed well and the result was excellent. The patient was presented to the section and showed few signs of so severe an operation. There was no spasm.

In two other cases the speaker had divided the spinal accessory nerve. In these cases, if this and massage failed, portions of the posterior branches of the cervical nerves should be excised.

Dr. Kocher, of Berne, had seen a good many cases, and had often seen a return after neurotomy. Therefore he had divided the muscles on both sides and effected a cure when neurotomy had failed.

Removal of the Gasserian Ganglion for Neuralgia.—Mr. Jonathan Hutchinson, Jr., reported a case of removal of the Gasserian ganglion for trigeminal neuralgia. The patient had suffered since 1882, with intervals of remission after various operations, such as stretching, neurotomy, and removal of Meckel's ganglion. Each time the neuralgia had returned, and the patient had finally become a morphinomaniac. The speaker performed Hartley and Krause's operation, lifting up the temporo-sphenoidal lobe of the brain to reach the foramen spinosum. A good deal of difficulty arose from oozing and the depth (two inches) from the surface; oozing increased so much that the final stage of the operation was postponed for one week. The ganglion was then removed in one piece, but the ophthalmic division was accidentally left behind. Recovery was uneventful. There was no return of the pain and the patient had gone to work again. There was only slight occasional twitching. There was complete anæsthesia in the region supplied by the fifth nerve. The only inconvenience arose occasionally when food got down between the tongue and the gum. All the teeth had been removed before. The sense of taste for bitter, salt, and sweet, etc., was lost. There was atrophy of the masseter and temporal muscles on the operated side. The opening in the bone had nearly closed up. No microscopic abnormality was found in the ganglion removed, except an excess of fibrous tissue.

There were two methods of getting at the ganglion: one from below, the pterygoid route, and the temporal or extradural route. The latter was the better. It needed a shorter incision and a comparatively small division of muscles. It was less disfiguring. It was safer. There was no risk of injuring the arachnoid or of interfering with the Eustachian tube. The pterygoid operation was much more dangerous and difficult.

If the Eustachian tubes were opened there was danger of sepsis; the dura mater and the internal carotid artery were also in danger. Moreover, the ganglion could not possibly be freely exposed and removed by this method. In his last case Victor Horsley was occupied for one and one-half hours, owing to adhesions. He now said that it was unnecessary to divide the middle meningeal artery, which could be drawn aside with hooks. This was a real improvement. Testimony was unanimous that when the ganglion was efficiently dealt with there was no return of neuralgia. The question of situation of the cause of the pain was most important. The object of this paper was to urge the adoption of this method, which, although difficult, was the best, and held out promise of relief in these distressing cases. In future he believed that the operation would be performed earlier, before the sufferings of the patients and the remedies used had undermined their health. Ligature of the carotid will no longer be considered in the treatment of neuralgia. No damage to the eye need ensue, if irritating antiseptics were not applied to the conjunctiva and cornea.

Mr. Mayo Robson said he had experienced the difficulties of the pterygoid route. He had operated in three cases, but believed he had not completely removed the ganglion in any of them. He thought this route would be abandoned in favor of the temporal one. By division and stretching of the inferior division of the nerve the ganglion itself was stretched, and so the other divisions were affected, and thus relief of pain, which might otherwise be permanent, was procured.

Nature and Treatment of Sciatica.—Dr. William Bruce read a paper on this subject. He said that the nature of sciatica was really unknown. Adhesions between the nerve and its sheath were said to be the cause, but sometimes after diagnosis of neuritis no adhesions were found post mortem. Exposure to cold and overexertion, especially the latter, were the most certain causes. He had notes of two cases seen in the last ten years, and was convinced that the pain was really due to hip-joint trouble. He had never found tenderness on pressure over the nerve, but often found it over the capsule of the hip. There were marked diminution of movement, especially of eversion, and wasting of the glutei. Other joints were often affected in the same patients. One hundred and ten cases had occurred in males, and one hundred and eight in females, in the latter generally about the climacteric period.

None of the drugs was very efficacious. Rest and recumbency and treatment of the uric-acid diathesis did most good, and spirit of turpentine exerted undoubted curative influence. All patients recovered in time. It was a surgical disease.

Dr. Crawford Renton read a paper on the "Surgical Treatment of Sciatica." In the case of a patient aged thirty-two, the nerve was stretched with partial improvement. There was pain when the patient walked, but little or none when at rest. Dr. Renton cut down on and examined the sciatic and internal and external popliteal nerves, and found large adhesions between the sciatic and its sheath and some on the popliteal. He removed these adhesions freely and the patient was cured. In seven other cases there were the same history, same operation, and same result. He wished strongly to urge that the nerve should be carefully examined for adhesions due to perineuritis, in which disease there was little or no pain when the limb was at rest. This was diagnostic between neuritis and perineuritis.

The President said that he wished sciatica were so simple a matter as Dr. Bruce said. He thought that nerve stretching was more successful, and that adhesions were less common than Dr. Renton believed.

Secondary Operations for the Relief of Musculo-Spiral Paralysis.—Dr. Robert Kennedy reported four cases of musculo-spiral paralysis with restoration of function after secondary operation. His first case was one of fracture of the humerus. He liberated the nerve from the callus and sensation returned in twenty-four hours. In a second, a similar case, there was gradual improvement. In the third case, also of fracture, sensation was not absent. He operated eleven months after the accident, but no improvement in motor power followed. The fourth case was one of rupture of the nerve. No radial nerve could be found. There was gradual return of complete power. He held that the return of conductivity dated from the restoration of sensation, the delay in the return of muscular power being due to changes in the muscles which it needed time to repair. If a year elapsed recovery of motor power was not likely. Asepsis was essential in these operations.

Mr. Mayo Robson remarked that he had grafted the tibial into the median, and a rabbit's spinal cord into the median of man paralyzed for far longer than one year, with success. No matter how long palsy had lasted, there was good hope of cure by suture or grafting. Physiologists and surgeons differed as to the possibility of return of sensation in twenty-four hours after suture. Although it might not be explained how it occurred, he was confident of the accuracy of his observations showing that it undoubtedly did occur.

Congenital Dislocation of the Hip.—Dr. Doyen, of Paris, showed his instrument for producing a new acetabulum, a tubular four-bladed drill, and a powerful screw apparatus for replacing the head of the femur in operations for congenital dislocation of the hip. He also showed a simple and useful iron frame to which patients were secured after this operation. It was of value whenever it was required to apply a plaster jacket round the trunk or limbs. For a description of the instruments he used in intracranial surgery he referred to Dr. Marcotte's thesis and his own book, "Technique Chirurgicale." He used a much greater electric power for his instruments than had been previously done, and saws of various sizes. Localization of any given convolution was still inaccurate; therefore his method by which he lifted up a flap consisting of a large part of the side of the skull was useful. The whole motor area could be exposed. In Jacksonian epilepsy, by Professor Reynolds' advice, he removed, after electrical explorations, the cortical motor centres of the extensors of fingers and wrist. A small glioma that no visual or tactile sensation had made them suspect was found in the centre of the piece removed. He had had very satisfactory results in cases of idiocy.

Coxa Vara.—Mr. Muirhead Little then read a paper with this title. After referring to Ernst Müller's original paper and to the nature of the deformity in this, an adolescent case, he said that afterward Lauerstein accidentally discovered in a rachitic child, post mortem, a deformity of the neck of the femur that he considered as the early stage of such cases as Müller's. These two cases were typical of two forms of the disease, that due undoubtedly to rickets in children, and that in adolescents following any disease that softened the bone. The drawings which he handed round showed how little the bone was deformed in the first class of cases, and how almost unrecognizable it was in the other. Mistakes in diagnosis were very frequent in coxa vara. Unless a skiagraph showed obvious diminution of the angle between the shaft and neck of the femur the diagnosis should only be provisional. He showed skiagraphs of cases diagnosed as coxa vara which were really congenital dislocations. Arthritis had been mistaken for coxa vara, and *vice versa*. The common curved rachitic femur, convex outward, had been taken for coxa vara.

Weight extension was the best treatment when the bones were soft. After they had hardened subtrochanteric osteotomy was the best. It was remarkable that so many cases had been recorded in Germany and hardly one in this country.

Mr. Noble Smith referred to a case of a girl of thirteen under his care, in whom *x*-rays showed very marked coxa vara. He proposed intertrochanteric osteotomy.

This closed the proceedings of the section.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PARLIAMENT AND VACCINATION—PROTECTION OPTIONAL—OTHER AGITATIONS—HYDROPHOBIA OR MUZZLING—INSTITUTE OF PREVENTIVE MEDICINE AND ANTI-VIVISECTIONISTS—ROYAL ARMY MEDICAL CORPS—HOSPITAL SUNDAY FUND—SUCCESS OF MR. BALFOUR AT GUYS'—DEATHS OF TWO SURGEON-GENERALS.

London, August 12, 1898.

The government has, to the disgust of many of its followers, completely succumbed to the fear of losing the votes of a few fanatics. Consequently vaccination is no longer compulsory. This surrender to the faddists on the part of the strongest ministry of the century is the more disgraceful, inasmuch as the house of lords provided a way of escape. As I reported last week, the upper house excised the conscience clause. The bill, therefore, was brought back to the commons, the amendments of the lords disagreed with at the instigation of the government, and the bill returned to them. On Monday the government whips had secured the attendance of a larger number of peers and thereby converted their minority of two into a majority of ten. In carrying the point the government has lost caste in the country, and alienated some of its own supporters.

It is plain to ordinary people that vaccination is not a question of conscience at all. Agitators may protest against coercion in sanitary matters, as they do; but coercion is of the essence of government. Let us have a conscience clause to relieve us from paying taxes when we object, and we should soon see the measure of conscience.

If a strong government yields, against its own expressed convictions, to the clamor of a few faddists,

can we wonder that in other things the country is beginning to protest that it has no backbone?

Vaccination is now optional for the next five years, and people are talking of the experiment. They forget that the effects will extend long after the five years. The children who are not vaccinated will grow up and be scattered through the population, affording a ready soil on which small-pox will flourish whenever a stray case may be introduced.

How the voluntary system will work is foreshadowed in recent events. Last Monday there were seventy-two cases of neglect to vaccinate before the magistrates at Matlock, but they were almost all adjourned, in consequence of the parliamentary proceedings. Again, at Spalding, a return of the vaccinations during the last six months shows the act to be a dead letter, as the guardians have abandoned prosecutions. Less than four per cent. of the children born have been vaccinated. No doubt many will be a little later, but there are hundreds of unprotected children in the union, and so it is in other unions.

Among the many papers which condemn the government for its action as to vaccination I may mention the *Daily Graphic*, which has issued a series of articles upon what vaccination has done. Commenting on the epidemic of Gloucester, the *Graphic* says: "The figures stand out as they stood out at Sheffield, with sufficient clearness to convince any man whose mind is not warped by the passion for faddism, or by the fear of faddist constituents." Such lessons as these may instruct weak-kneed politicians.

The appeal made to the mothers as to the temporary inconvenience is as insincere as are other appeals to human selfishness, of which we see too many examples. One is the continual whine kept up about muzzling the dogs. Just now the newspapers are getting up a cry to take dogs for a holiday where muzzling is unknown, and various resorts are proclaiming their freedom from the restraint. One may well doubt whether this tenderness for the dogs' discomfort is not assumed as a veil for selfishness. It is so much trouble to the owner to look after his dog. To avoid it he is willing to risk hydrophobia in his neighbors. He objects to stamping out the disease by anything that gives him temporary annoyance, and oh, selfish hypocrisy! to conceal his motives declares there is no danger. If only some of these selfish men and women could see a case of hydrophobia, and then incur some risk to their own bodies, we should hear no more protests against muzzling.

There is another agitation going on, which is somewhat related to the last named. The antivivisectionists had a meeting in Chelsea to protest against a license being granted to the Institute of Preventive Medicine. A good deal of nonsense was talked, and not a little unparliamentary language employed. "Cursed atrocities" was a favorite phrase, and medical theories were denounced as the "gospel of salvation by filth." Canon Wilberforce inculcated the doctrine of the immortality of animals as well as of men, founding on it a declaration that we are intrusted with the welfare of our dumb brethren. The dispute has passed on to the local newspapers, and Dr. D. Vinrace has written in defence of vivisection as it is now practised by skilled men under legal precautions against abuse. He challenges his opponents to show that it is less justifiable to inflict pain for the purpose of alleviating human suffering than it is to do so in order to provide food for our bodies, or still more for the purposes of sport. Of course all this has been said before, but the antivivisectionists continue to misrepresent the facts, and heap abuse on all who do not agree with them.

Surgeon-Major Gardner has written to the *Morning Post* to inform intending aspirants for the Royal Medical Corps "that if they resign on the gratuity of £1,800 at fifteen years' service they will still be liable to be called upon to serve." Combatants are not liable to recall. It would certainly be awkward for a retired medical officer to be recalled, if he had gone into civil practice.

The hospital Sunday fund has a falling off of about £5,000 this year. Various explanations are offered by its supporters, the favorite one being the competition of the Prince of Wales' fund. Sir Sydney Waterlow adopts this notion, but Sir H. Burdett ridicules it. Neither of them seems to perceive that discontent with the decisions and the treatment meted out to deputations has much to do with it. Sir S. Waterlow's prejudices against specialists render his manner of receiving them objectionable, and the secretary of the fund, taking his cue from the chairman, can be most offensive.

Mr. Balfour's speech at Guy's was a remarkable success, for one of the audience has presented $6,000 to be used for the endowment of medical research, advocated in Mr. Balfour's address.

The death is announced of Surg.-Gen. John Murray, at the age of eighty-eight. He was in due course an inspector-general of hospitals in the northwest provinces of India. He retired in 1871. He was an authority on cholera, and initiated the plan of moving troops from barracks to camp as a means of meeting epidemics.

Surg.-Gen. J. F. Beatson, C.I.E., died on the 29th ult., aged eighty-one. He retired in 1880 after thirty-five years of service in India.

HEALTH BOARD AS A PART OF THE ARMY MEDICAL CORPS, DISTINCT FROM THE HOSPITAL SERVICE.

To the Editor of the Medical Record.

Sir: The outbreak and the continued spread of yellow fever, typhoid fever, and dysentery in the camps about Santiago after the cessation of fighting, when the conditions ought to be controllable; the outbreak, in epidemic form, of typhoid and dysentery in the camps of instruction at home, at camps Thomas and Alger and at Tampa and Fernandina, raise the question whether the time has not come for a radical change in the medical organization of the army, and for the formation of a sanitary or health board distinct from the hospital service.

In civic bodies it has long been recognized that the essential prerequisite for effective prevention of disease is a thorough expert knowledge of preventive medicine; it has been found necessary to separate in practice this department of medicine from the practical treatment of disease. In most large cities and towns boards of health have been established, and to these has been given the power to make sanitary regulations and to enforce them.

The successful prevention of disease requires expert knowledge not ordinarily possessed by the practising surgeon, experience in its application, and power to compel observance of systematic methods.

It is difficult to understand the apparent lack of thought given to this question, when we consider the ease with which an epidemic disease may destroy the usefulness of an army. Apparently military men give untiring attention to increasing the effectiveness of the army organization, and, in action, to preventing any useless sacrifice of lives, only to allow this organization to be undermined, and more lives uselessly sacrificed by preventable causes, than could possibly result from the fire of the enemy. We have just seen a fine army at Santiago practically destroyed, so far as

effective fighting is concerned, after the victory was won and the soldiers were returned to camp.

We have seen it necessary to remove the entire army to this country to save it from destruction. The diseases which brought this about were, according to the published army reports, malaria, typhoid fever, dysentery, and, in a lesser degree, yellow fever. It is not in the power of any one at this distance to say whether these diseases could have been prevented, under the conditions prevailing. But it is hard to understand how typhoid and dysentery, at least, could have got beyond control in well-ordered camps.

At any rate, there is no excuse for the prevalence in epidemic form, or in a conspicuous amount, of preventable diseases like typhoid fever and dysentery in camps of instruction, and if such diseases prevail it means inefficiency on the part of the authorities. It is even debatable whether yellow fever should not be classed equally with these diseases as preventable, if it is found to spread in a camp as an epidemic. It is certainly an open question whether any given epidemic may not have been due to conditions which might have been foreseen, and for which some one is responsible.

Camps of instruction, like those at Montauk and Chickamauga, ought to be ideal places for sanitation, and for controlling what are known as preventable diseases. The site can be selected after a thorough study of the ground. The qualities of water supply and the soil can be completely known. The neighboring water supplies, such as the wells in adjoining farms and springs from which the soldiers are liable to drink, can also be known and examined. With the absolute military authority possessed by the commanding general, and plenty of men at his disposal, it is perfectly easy to station guards over dangerous water supplies. Contagious diseases can be isolated in the open air, regiments separated from one another, and all intercourse forbidden by armed guards; the food supply can be absolutely controlled.

Further, and by no means the least advantage possessed, the opportunities for tracing the outbreak of an epidemic, if such should occur, are such as are rarely present in civic communities. With military officers and surgeons galore; colonels, captains, sergeants, corporals, it should be easy to trace nearly every case to its source.

What more can any sanitarian ask for, and what wouldn't a civilian board of health give for such power and such enormous resources? The health authorities of a city must take the conditions as they find them—the water supply, the drainage, the habits of life of the individual; but the military authority of a camp has it in his power to control all. In the field, where nearly everything must be sacrificed to the exigencies of winning the battle, and for which everything should be sacrificed, even the wounded and the hospital service, it may be questionable whether much can be done in the way of effective sanitation.

But it is in the camps, and to these I am now referring, that, by the confessions of the Washington authorities, typhoid fever exists to an extent for which there ought to be no excuse.

Surgeon-General Sternberg himself, in one of his circulars says: "The extensive prevalence of typhoid fever in camps of instruction indicates that the sanitary recommendations made in this circular have not been carried out. If medical officers have failed to make the proper recommendations as indicated, the responsibility rests with them. If the recommendations have been made, and not acted upon by those having authority in the various camps, the responsibility is not with the medical department; but these recommendations should be repeated and commanding officers be urged to move their camps at frequent intervals and to maintain a strict sanitary police."

The cause of the condition of affairs is not difficult to find. It lies in the continuation of a system long since abandoned in civil life. The army organization expects that the army surgeon shall be sanitarian, as well as surgeon and physician, and it relies on a multiplicity of regimental officers, each representing semi-independent authority, so far as sanitary matters are concerned, for originating and enforcing measures for protection. The average physician has a limited knowledge of expert sanitation, and practically no experience in dealing with the problems of the suppression of disease. The difference of opinion among medical men in such matters—I do not mean expert sanitarians—is as diverse as were the colors of Joseph's coat.

The answer which is sure to be made to this is that "general recommendations" issued from headquarters, which it is expected that subordinate division and regimental officers shall carry out, are not satisfactory. Therein lies not the whole, but an active factor in the present ineffectiveness. It is expected that these orders will be carried out; commanding officers are to be "urged," says Surgeon-General Sternberg. But if they are not carried out, what then? Why, as General Sternberg says, "it indicates that the sanitary recommendations made in this circular have not been carried out." But meanwhile typhoid, dysentery, and yellow fever go on claiming more victims.

The underlying cause of this condition of things exists, I believe all sanitarians would say, in the system of organization which lacks a central supervising authority competent and with power to make regulations, and to enforce them without deference to the good will and co-operation of a multitude of regimental military officers, and which intrusts the treatment of the sick for disease, the surgical operations for wounds, and the prevention of contagious diseases to one and the same body of men. The separation of these different departments has long been made in civil life, and there is no good reason why the sanitary department should not also be separated from the hospital service in the army.

A more efficient system than the present one would plainly be that which has been adopted in civil life. A sanitary board, distinct from the hospital service, and endowed, under proper limitations, with ample power not only to make regulations, but to compel their enforcement by the military department might be easily introduced in the army. There should be for each corps a sanitary department, consisting of either an expert sanitarian with staff or of a board of health officers, which should have the same relation, so far as altered circumstances permit, to the army organization that a health board bears to a city.

Such a board would have advisory functions in the selection of the site of camps of instruction, would investigate the origin and spread of contagious diseases, regulate the sale of dangerous articles of food by sutlers, select and guard the water supply, quarantine the sick, isolate commands in which some suspicious disease has broken out, and generally contrive the sanitation of camps. It would of course be subject to the authority of the commanding general and probably be a part of his staff, and perhaps issue its orders in his name.

It is not difficult to point out specific instances, even with a limited knowledge of the local conditions, in which during this war the services of such a department would have been of value. No expert sanitarian would have allowed such a site as that of Camp Alger to be selected, or would have allowed troops to be sent to any camp before there was a water supply; sutlers would not have been allowed to sell to the soldiers at Tampa and Camp Alger lemonade made from

the water of God knows what wells, with the risk of spreading typhoid.

It is safe to say that the houses in which some of our officers are said to have contracted yellow fever at Siboney, and which were later burnt by General Miles, would never have been occupied; and it is hard to believe that typhoid (probably contracted from old polluted wells in the neighborhood of the camps) would ever have become "widespread" at Tampa, Chickamauga, Fernandina, or elsewhere.

This is not a humanitarian question alone. For a civilian it is painful enough to know of the hundreds of lives ingloriously lost, after the fighting was done, and the health of thousands injured for the remainder of their lives, not by bullets, but by preventable diseases. History has shown that these diseases kill more of the troops than bullets. This is painful; but it strikes the average civilian as crass stupidity that the authorities in control should allow a command to be crippled, and its force as a fighting instrument weakened, by preventable causes. It is only fair to say that the present system of army sanitation was probably as good as could have been devised in the early periods of our army history, and perhaps represented the best sanitary system of those times. But the enormous advances made of late years in our knowledge of the causation of epidemic disease has led to the formation of separate departments in civic bodies for the distinct purpose of preventing disease, and the success in accomplishing this has amply justified this policy. It would seem now to be a question whether a progressive nation should not initiate civic bodies, and intrust to a corps of expert sanitarians, distinct from the hospital service and with ample power, the task of preserving the lives of its soldiers from the attacks of disease and the efficiency of its armies as fighting machines.

458 Beacon Street, Boston, August 17, 1898. MORTON PRINCE, M.D.

RHUS POISONING.

To the Editor of the Medical Record.

SIR: I have read Dr. Louis F. Frank's article on Rhus toxicodendron, and quite agree with him in his method of treatment. I also read the article by Dr. A. F. Hudson, in the MEDICAL RECORD of July 30, 1898. I will add that for at least fifteen years I have applied muriate of ammonium in about the same solution and in the same way, and have found it probably the most soothing application that I have ever used. I believe, however, that the action of the poison is self-limited, and that muriate of ammonium will therefore not act as a curative or a prophylactic agent.

Iowa City, Ia. J. B. KESSLER, M.D.

AN IMPROVISED SUSPENSORY BANDAGE.

To the Editor of the Medical Record.

SIR: In these earlier days of our war, when unpreparedness is of necessity a misfortune which all concerned have had unavoidably to encounter, I have been consulted by numerous officers and soldiers for advice to relieve the pendent state of the scrotum and testicles, caused by relaxation due to hot climate, perspiration, etc. In the absence of the suspensory bandage I have devised and advised the following simple resource, viz., to fold the centre line of the front shirt-tail vertically, and sew horizontally a seam about four inches long about two inches below the root of the penis when the man is standing erect, making, as it were, a shelf for the scrotum and testicles to lie upon. A round hole can be cut in front to project the penis through for urinating. Soldiers as well as others dislike the use of the suspensory or any other troublesome harness. Now here is a simple device, fulfilling readily all the requirements for pendent scrotum or varicocele, and it is all that can be practically desired for the purposes intended. I hope in this brief note I have made the idea clear to your readers.

W. H. DALY, M.D.

Major and Chief Surgeon, U.S.V., serving on General Miles' Staff, Headquarters of the Army of Porto Rico.

On Board United States Army Transport Ship "La Grande Duchesse," Approaching Porto Rico, July 6, 1898.

APOMORPHINE.

To the Editor of the Medical Record.

SIR: I have read the articles in the MEDICAL RECORD relative to the virtues of apomorphine, and wish to state that in two cases of morphine poisoning I found it perfectly useless. In each case I injected one-tenth grain, and in one case repeated the dose in a little while, but could get no result at all. My idea is that the narcotic effect of the opium deadens the vomiting-centre so much that apomorphine will not excite it. Both of these patients vomited after taking ipecac and zinc sulphate in warm water. I have every reason to think that the apomorphine was good, as it was from a first-class house. F. W. VAN DYKE, M.D.

Grant's Pass, Ore.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 27, 1898:

	Cases.	Deaths.
Tuberculosis	149	156
Typhoid fever	180	41
Scarlet fever	69	6
Measles	30	2
Diphtheria	96	14
Chicken-pox	8	0
Cerebro-spinal meningitis	0	7
Laryngeal diphtheria (croup)	1	2

Consumption and Marriage.—In an article in a London weekly paper on consumption and heredity, Dr. Wilson says: "I suppose in a higher era of things we may hope for disapproval of marriages between those who come of a tuberculous stock, or between any healthy and any tuberculous individuals—that is, assuming the taint to be present on one side only. The danger of unions of the latter type is that the affected partner may infect the healthy one. Affections are the last items in the category of human emotions to bear being talked to or advised by science, and I have therefore discounted any criticism of my opinions by assuming that it would only be in a higher era of things when the value and nobility of health are better appreciated, that people will refrain from unions that can only result in the propagation of disease. What applies to tuberculosis in this aspect of affairs applies to many another hereditary ailment. I often think of the sarcasm with which a philosopher from another planet might greet our practice on this, when he witnessed the intense and jealous care with which we insure the health and physical perfection of our horses, cattle, sheep, dogs, and even our pigeons, while as regards our own hereditary history we are absolutely careless. It is an old, old story this, the problem of inheritance; but despite the plain evidence that disease can be and is transmitted often to the utter undoing of a family, we proceed placidly to ignore all the teachings of science in the matter and raise races of weaklings, born only to die prematurely."

Francis Bacon's Warts Cured by Bacon.—The takinge away of Warts, by Rubbinge them with some what yt afterwards is put to wast, and consume, is a com'on exp'ment. And I doe apprehende it the rather because of mine owne exp'ience. I had from my Childhood a wart uppon one of my Fingers: Afterwardes when I was about sixteen years old, being at Paris, there grew upon both my handes a number of Warts (at ye least 100) in a Moneths space. The English Embassadours Lady, who was a woman free from sup'stition, told me, one day; she would helpe me away with them. Whereupon shee got a peice of Larde, wth ye Skin on, and rubbed ye Warts all over, wth ye fat side; and amongst ye rest yt Wart wch I had had from my Childhood; Then she nayled the Peice of Lard wth ye fat towards ye Sunne upon a Poast of her Chamber window wch was to ye south. The Successe was, that wthin five weekes space, all the Warts went quite away: And ye Wart wch I had soe longe endured for Company. But at ye rest I did little marvaile, because they came in a shorte time, and might goe away in a short time againe. But ye goinge away of yt wch had staid soe longe doth sticke with me yet. They say ye like is done by rubbinge of Warts wth a greene Elder sticke, and then buryinge the sticke to rot in mucke.—*Notes and Queries.*

An Ancient Hospital.—A very interesting discovery is announced from Baden near Zurich. The learned have been discussing for ages whether anything in the way of hospitals was known to the ancients. It is not to be said that they have been disputing, for there was not enough material hitherto to support a lively argument. One might read the whole of Greek and Roman literature carefully without noticing one passage that might be interpreted as an allusion to a hospital. The works of Hippocrates could not fail to speak of them surely if any existed, but nothing is there beyond a reference to the notes of "cases" observed in the Temple of Æsculapius. So it is generally assumed that there were no hospitals in those days; the æsclepia were simply baths where massage was given. We now learn from the London *Standard* that there has been discovered at Baden a hospital containing "fourteen rooms supplied with many kinds of medical, pharmaceutical, and surgical apparatus, probes, tubes, pincers, cauterizing instruments, and even a collection of safety pins for bandaging wounds," but these things are familiar. "There are also medicine spoons of bone and silver, measuring-vessels, jars and pots of ointment, some still containing traces of the ointment used." The latest date of the coins found appears to be in the reign of Hadrian. Probably it was a military hospital, for this was the station of the seventh and eighth legions. But the find is certainly not less interesting on that account, for the army medical service of Rome and Greece is one of the deepest mysteries of archæology. Cæsar refers only once to his regimental surgeons; is there a single distinct allusion elsewhere? We hail with puzzled gratitude the casual remark of Xenophon, that the Spartans sent their doctors to the rear when a fight impended, but we look vainly for more information from him or anybody else.

Algæ in Drinking-Water.—In a work on the algæ of the Hamburg waterworks, Herr O. Strohmeyer states that the green algæ—Cladophra, Spirogyra, Enteromorphra, Stechococcus, etc., have a very powerful effect in purifying water by the destruction of bacteria through the agency of the oxygen which they exhale. Those algæ, on the other hand, which are inclosed in a mucilaginous sheath, especially diatoms, have a very prejudicial effect on drinking-water by the filters clogging.

Antisepsis in Excelsis.—We have heard of medical men wrapping themselves up in sheets and putting towels round their heads when visiting patients suffering from infectious disease, regardless of the feelings of sensitive patients at such an apparition, but certain surgeons abroad seem anxious to imitate the myrmidons of the Inquisition, and before performing any surgical operation they don hoods or capotes with no opening except for the eyes in order to guard against the "rain of bacteria" which might follow the accidental brushing of the operator's head against that of an assistant. In mercy to the patients it is to be hoped that they do not assume this ghastly attire until the former have been fully anæsthetized. A photograph of a group of surgeons in full canonicals bending over the emaciated body of some hapless patient would, if properly placed on view in a populous thoroughfare, certainly have a *succes de curiosité.*—*The Medical Press.*

The Purity of London Water.—In a report which will shortly be presented to the London county council the water committee recommends that the council's chemist should be authorized to make for a certain period a daily microscopical examination of the water supplied by each of the metropolitan water companies. At present the examinations are made three times a week, and the committee states that as a result of such examinations made between January, 1897, and May, 1898, it has been noticed that considerable improvement has taken place in the quality of water supplied. This is stated by the chemist to be in some degree due to the increased storage room secured by some of the companies, thereby obviating the necessity of taking water from the river during storm periods, and also undoubtedly to a much greater extent to the improvement in the mode of filtration adopted by the companies. The chemist also points out that there has been an improvement in the microscopical and bacteriological character of the water in 1898, although there is yet much to be desired in that direction. On many occasions anguillulæ, rotiferæ, portions of insects, decaying vegetable matter, and dyed fibres had been found, which certainly should not be present in efficiently filtered water when drawn from the mains. He gives several instances in which during the past seventeen months the water supply when drawn from the mains of some of the companies had been unfit for drinking-purposes.—*London Times.*

Ether Tippling.—The medical officer of health for the district of Heydekrug, in Lithuanian Prussia, has recently drawn attention to the fact that ether tippling is excessively prevalent and constantly increasing. He ascribes this to the fact that the recently increased excise duties have advanced the price of spirits and practically inhibited their use among the lower classes, who are chiefly of the Slav race. It is added that the vice is an importation from Russia, it being very prevalent in some districts of the Muscovite empire. Children, it is declared, often come to school exhibiting signs of having imbibed ether before leaving home. Mothers give it to their offspring to relieve abdominal pain; and on market days the odor of the drug is perceptible everywhere in the respiratory exhalations of the peasantry of both sexes.

Dangerous Visits.—The trial of a doctor's suit was published in a Connecticut newspaper some years ago, in which a witness was called for the purpose of approving the correctness of the doctor's bill. The witness was asked by the lawyer whether the doctor did not make several visits after the patient was out of danger? "No," replied the witness, "I considered the patient in danger so long as the doctor continued his visits."—*The Sanitarian.*

Do Women Perform Illegal Operations on Themselves?—To many doctors the idea of an unskilful woman being guilty of an attempt to perform an illegal operation on herself indicates such an amount of fatuous folly as to appear almost incredible. In view, however, of the prominence which "illegal operations" are enjoying at present and the circumstances attending some of them, it becomes important to question whether or not the presence of a perforated wound into the peritoneum, through or in the vicinity of the uterus, implies a second person as operator. It is very difficult to obtain reliable evidence on such a point, but the evidence to be had leads to the belief that women not infrequently attempt to procure abortion for themselves by illegal methods. For this purpose they use such dangerous implements as bonnet pins and the like, and the ease with which they thus provoke internal hemorrhage acts as an encouragement to them to persevere in their efforts. The sensitiveness of the uterus and the upper part of the vagina is not at all great, and it is by no means unlikely that a resolute woman might endure the pain inflicted in producing a perforated wound.—*Medical Press and Circular.*

The Red Cross Society.—In view of the magnificent past record of the Red Cross Society and of the good work now being done by its members, a short sketch of its founder may be interesting. Much ignorance prevails as to the origin of the society; in fact, many persons are unaware of even the name of its initiator. The honor of the first conception of such a society belongs to J. Henri Dunant, who was born at Geneva on May 8, 1828. His family had done the State service for more than two centuries. When quite a young man he devoted himself to philanthropic work among the poor of his birthplace. Deeply impressed by Miss Florence Nightingale's work in relieving the sick and wounded during the Crimean War, he was still more vividly stirred by the sufferings of the wounded at the battle of Solferino, of which he was an eye witness, and which he described in a pamphlet entitled "Un Souvenir de Solferino." The number of wounded at this engagement reached the appalling figure of twenty-two thousand, and, the surgeons available being quite unable to attend to so great a body of men, the consequence was that most of them were compelled to remain for days on the field without medical care or nursing of any kind. M. Dunant described this terrible state of affairs in such graphic language that a thrill of horror went through the civilized world. He also demonstrated that no army medical service could be expected to stand such a strain on its resources as at Solferino, and suggested that the military medical service in all armies should be supplemented by volunteer aid societies. In furtherance of this scheme he in 1863 made a pilgrimage at his own expense through the different countries of Europe, for the purpose of enlisting the support of the sovereigns, ministers, and other great and rich persons. Finally through his efforts, in October, 1864, the historic conference was held at Geneva, from which sprung the convention and the Red Cross Society. There is a good deal of misconception with regard to the rights conferred by wearing the badge of the Red Cross. As a matter of fact the Geneva congress declined to consider the question of independent volunteer aid societies being placed under the convention, but carefully confined its privileges to the medical services of the armies engaged. Surgeon-Col. W. F. Stevenson, of the British army, in his excellent treatise on wounds in war, defines the duties of the Red Cross Society. Very clearly he says: "The notion is far too common that the Red Cross is a civil distinction, that it is a sign which may be carried by private individuals and by members of non-military societies, indicating that they are qualified to aid sick and wounded persons; and the uses to which it has been and unfortunately is being put foster this misapprehension. Civil nurses wear it; it is placed on the labels of bottles of quack medicine, and its employment is often quite apart from military medicine and surgery. All this is wrong. Persons who in this way mark themselves or their goods with the Red Cross make use of a sign to which they have no right or title, and do it in absolute ignorance of the meaning of their actions. The Red Cross is as purely a military distinctive mark as is any regimental badge worn as a part of a soldier's uniform." In a word, the Red Cross Society was intended as an adjunct to the regular-army medical establishment, and was meant always to be subject to the control of the general in command.

Language of the Eye.—Louis Robinson, in a recent number of *Blackwood*, gives the result of some of his investigations on this subject. He observed that the pupils of a fox terrier, when teased beyond endurance, became greatly dilated, and that the eye chambers reflected light in exactly the same way as that of the human being when under the dilating influence of belladonna. He discovered the same phenomena extended to cats and monkeys when enraged and meditating mischief, but that when making an attack the pupils became suddenly contracted.

The Puritans Not Teetotalers.—That our Puritan forefathers did not believe in the healthfulness of water as a beverage would seem probable from a copy of a record of the town of Beverley, Mass., on the occasion of a minister's ordination in 1785. It is as follows: "Thirty bowles of punch before they went to church, £3; 80 people eating in the morning, at 16d., £6; 10 bottles of wine before they went to meeting, £1 10s.; 68 dinners at 30d., £10 4s.; 44 bowles of punch while at dinner, £4 8s.; 28 bottles of wine, £2 14s.; 8 bowles of brandy, £1 2s.; cherry rum, £1 10s.; and 6 people drank tea, 9d."

Health Reports.—The following statistics concerning small-pox, yellow fever, plague, and cholera have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending August 27, 1898:

		Cases.	Deaths.
Small-Pox—United States.			
Alabama, Mobile	August 3d to 17th	5	
New Mexico, Albuquerque	August 13th	15	
Small-Pox—Foreign.			
Australia, Sydney	July 9th to 16th	..	1
Belgium, Liege	July 23d to 30th	..	1
France, Nantes	July 1st to 31st	..	1
Paris	July 31st to August 6th	..	1
Honduras, Tegucigalpa	July 16th to 23d	1	
India, Calcutta	July 9th to 16th	..	1
Madras	July 9th to 16th	..	1
Russia, Odessa	July 23d to 30th	3	
St. Petersburg	July 23d to 30th	5	2
Warsaw	August 1st to 8th	..	6
Sweden, Christiania	July 23d to 30th	1	
Uruguay, Montevideo	July 8th to 16th	2	
Yellow Fever—United States.			
Florida, Tortugas Quarantine	August 18th	1	
Georgia, South Atlantic Quar.	August 21st	1*	
Louisiana, Franklin	August 23d	1	
Yellow Fever—Foreign.			
Brazil, Rio de Janeiro	July 1st to 8th	29	20
Colombia, Cartagena	July 1st to 31st	5	4
Mexico, Tampico	August 7th to 14th	3	17

THE ELIMINATIVE TREATMENT OF TYPHOID FEVER—A REPLY TO A RECENT CRITICISM OF THIS METHOD.

BY W. B. THISTLE, M.D., L.R.C.P. LOND.,

TORONTO, CANADA,

LECTURER IN CLINICAL MEDICINE AND DISEASES OF CHILDREN IN THE UNIVERSITY OF TORONTO; PHYSICIAN TO THE VICTORIA HOSPITAL FOR SICK CHILDREN AND TO THE OUT-PATIENT DEPARTMENT, TORONTO HOSPITAL.

IN a recent paper on "Some of the Intestinal Features of Typhoid Fever,"[1] Dr. Osler refers to the eliminative plan of treatment as follows: "We have possibly been too fearful of the dangers of the use of purgatives in typhoid fever. The experience of a great many men who have adopted the eliminative method of Thistle, or who have given salines or calomel freely, shows that the mortality is not materially increased over that from the ordinary symptomatic plan. My contention, however, is that they are not indicated, as it is not likely that the typhoid bacilli multiply and develop their poison to any extent in the intestinal contents themselves."

The first sentence in the above quotation would seem to indicate a remarkable change in the mind of the distinguished author regarding the use of purgatives in typhoid fever. Hitherto their use has been denounced by him as "wrong in theory and dangerous in practice." Now, accepting the experience of a large number that the practice of giving purgatives in this disease is not dangerous, and thus having got rid of "the lion in the way," he still maintains that their use is wrong in theory. The eliminative and antiseptic method of treatment has on other occasions received some attention at the hands of Dr. Osler, but always in the way of denunciation and adverse criticism.

To this course one could not possibly have the slightest objection but for the fact that the criticism has been directed, not against the theory advanced, but against what the objector supposed to be the theory. From the consistent way in which the theory of eliminative treatment has been misstated and misunderstood by him,[2] the only inference open is that my papers on the subject in which the theory involved in this plan of treatment was set forth had unfortunately escaped his notice.

The quotation from his recent paper, given above, illustrates admirably what I have just stated. His contention that purgatives are not needed, because he considers it unlikely that the typhoid bacilli multiply and develop their poison to any extent in the intestinal contents themselves, would imply that in carrying out this plan of treatment purgatives are given with the sole purpose of clearing typhoid bacilli and the poison generated by them from the intestine.

Such is not the case, and it is manifestly a misrepresentation of the theory of eliminative treatment to convey any such idea to the mind of the reader. In all my published papers I have taken the utmost pains to combat this error and to point out that the idea of elimination by means of purgatives must not be limited or confined to the simple clearing of bacilli and toxins from the intestine, but must also embrace withdrawal of toxins from the body by way of the intestine. In short, elimination in typhoid fever must be understood in the same sense as elimination in, for example, lead poisoning.

The idea in the use of purgatives in the treatment of typhoid fever, if I may be permitted again to outline the theory, is:

I. To facilitate throughout the entire duration of the disease elimination of toxins from the body.

II. To clear out the intestine at the earliest moment, carrying away bacilli and toxins which would otherwise in all probability go to increase the existing infection and intoxication of the body.

III. To keep the intestines as free as possible from bacilli and toxic substances, thus preventing to a great measure reinforcement to the bacilli and toxins already located in Peyer's patches, the solitary glands, mesenteric glands, spleen, and other parts of the body.

IV. To maintain the bowels free from bacilli, of all kinds, and from accumulations of decomposing and toxic substances, and thus to enable the liver to exercise its poison-destroying and depurative functions to greater advantage against the poisons produced by the colonies of bacilli situated in the lymphatic structures, spleen, or elsewhere in the tissues and fluids of the body.

Modern physiology has made it clear that one of the greatest functions of the liver is to intercept and destroy or cast out of the body toxic substances found in the circulation.

The toxic substances must of course be carried to the liver either by the blood stream in the hepatic artery or by the veins of the portal system.

As a result of this poison-abstracting function of the liver, the pint or more of bile daily poured into the intestine is under ordinary circumstances in the healthy body highly toxic. Semmola and Giofiredi in their recent work on "The Physiology of the Liver and the Function of Bile," in the "Twentieth Century Practice,"[3] accept the estimate made by Bouchard, that the bile is under ordinary circumstances nine times as toxic as the urine.[5] They also draw attention to the fact that in case of bacterial invasion, such as typhoid fever, the toxicity of bile becomes immensely increased.[6]

It is therefore most reasonable to assume that by frequently and repeatedly clearing from the intestine this highly toxic bile the sum of poison in the body is lessened, for, be it remembered, if the bile poured into the intestine be not carried on out of the intestine, it to a great degree becomes reabsorbed, and thus the effort of the liver to free the body of the toxic substances is in a measure rendered nugatory.

In the case of the typhoid toxin Semmola and Giofredi quote Roger as having demonstrated that it actually is intercepted by the liver.[7]

Clearing out the intestine and maintaining it as free as possible from all forms of bacilli and toxins indirectly assists the depurative function of the liver, for the less the amount of poison carried by the portal system from the intestinal tract, the more effectually

will the liver deal with the toxins in the general circulation. This scavenger function of the liver is, however, exercised within certain limits, and if excessive quantities of poison should be carried from the intestine the function may be taxed to the full; and so the liver will be unable to deal with the toxins in the systemic circulation. Or, again, the portal blood may carry so much toxin from the intestine as completely to overwhelm the liver, so that it is able neither to guard the portal entrance nor to intercept toxins coming through the general circulation. The irritation of hepatic tissue in this way would seem to furnish an explanation of the tenderness and enlargement of the liver sometimes noticed during the course of typhoid fever.

Consideration of these facts in hepatic physiology cannot but impress one with the desirability of constantly clearing away the toxic bile and of keeping the intestine as free as possible from bacilli and toxic substances throughout the entire duration of the disease. It also shows the wisdom of employing intestinal antiseptics and of exercising care in the arrangement of the patient's food, so that the least possible residue may escape assimilation and remain in the intestine to undergo decomposition.

The antiseptic substances chosen should, however, be the least harmful, for, if poisonous substances are selected to purify the intestine, they themselves become a tax upon the liver. I have before pointed out that toxic antiseptics—*e.g.*, salol—can be used much more freely if at the same time purgatives are employed frequently.[8]

Elimination of toxins by way of the intestinal canal, although mainly through the medium of bile, occurs to a very considerable extent through the serous exudate from the intestinal wall.

None, I imagine, will question the correctness of this view. In a condition such as typhoid, where the fluids of the body hold in solution excessive quantities of toxic substances, the serous exudate into the intestine in response to purgatives must of necessity bring with it some of the toxins. Purgatives, then, facilitate elimination of poison from the body through the toxic bile, and to a lesser degree perhaps through the toxic serum.

One cannot leave the consideration of this subject without noticing the indispensable relation which the giving of large quantities of water bears to the use of purgatives in this scheme of elimination. Unless care be exercised in this matter the fluids of the body would be drained off, to the serious disadvantage of the tissues. Moreover, the toxins in the body would become more concentrated and therefore more harmful.

A moment's reflection will show the wisdom of this course during the employment of purgatives, in this way replacing the toxin-laden fluid which has been carried away.

Although the purpose of this paper is to indicate the use of purgatives in the treatment of typhoid fever, yet in the eliminative plan of treatment which I have advocated the excretory function of the kidneys was not lost sight of, and it was shown that elimination of toxins by the kidneys is facilitated by the giving of large quantities of water.

I have before also advocated the use of calomel, in connection, of course, with salines, because of its excellent diuretic action.[9] It consequently promotes elimination through both the intestines and the kidneys.

To summarize, the use of purgatives in typhoid fever and the purpose of the eliminative plan is:

1. To limit the original infection and intoxication of the system generally.

2. To carry away the toxic bile as it is poured into the intestine.

3. To promote elimination through the medium of the serous exudate into the intestine.

4. To promote excretion of toxins by the kidneys.

5. By lessening the toxæmia, to increase the resistance and aggressive action of the tissues. (I have before drawn attention to the fact that the aggressive and defensive action of the cells must be in inverse ratio to the degree of toxæmia.[10])

6. To prevent excessive accumulation of bacilli (typhoid bacilli, colon bacilli, etc.) and toxins in the intestinal glands, thus lessening the likelihood of extensive necrosis and ulceration, and the dangers incidental to that condition.

7. By maintaining the intestine as free as possible from bacilli and toxins, and frequently clearing it out to lessen the work thrown on the liver from the portal side, and thus to enable it to exercise its depurative function more fully in the interception of poisons in the general circulation.

8. To lessen the chance of death from exhaustion due to the long-continued action of large quantities of poison on the tissues.

9. To lessen the amount of poison in the body and avert the danger of death from excessive accumulation of toxin, *i.e.*, acute toxæmia.

10. To prevent the discomfort and danger arising from accumulation of gases in the intestine.

11. To prevent or control diarrhœa. Whether the diarrhœal flux be due to bacilli or irritant matter in the intestine or is the physiological result of toxic substances in the system, in either case the action of purgatives would be beneficial. In the one case the irritants, whatever their nature, are removed; in the other the systemic toxæmia is lessened.

12. By keeping toxæmia at the lowest possible point, the functions of digestion and assimilation are less interfered with and nutrition is better maintained.

Dr. Osler will have it that the advocates of the use of purgatives and antiseptics look upon typhoid fever as a disease of the intestines, while he himself would be with those who have learned within the last few years that it is an infection of the system generally. Such an assumption is entirely unwarranted. My own position has always been that typhoid fever is a disease primarily of the intestines, the bacilli first invading the tissue in the intestinal wall and afterward reaching all parts of the body. Although primarily a disease of the intestine, it quickly becomes a general infection. So great an authority as Prof. Sydney Martin adheres to that view of the question, and considers that "the arguments advanced in support of the belief that typhoid fever is a general infection with a secondary intestinal lesion, are not very satisfactory."[11]

He considers that, "from our knowledge of other intestinal infections, the view that the infection in enteric fever is primarily intestinal is the more logical."

That intestinal ulceration is not an essential or necessary feature in typhoid fever I fully believe. I advanced that view in my paper published in the MEDICAL RECORD of March 1, 1894, and pointed out that if the intestine be thoroughly cleared the process of infection is interrupted, the local infection of the gland to some degree limited, and as a result the glandular tissues are more likely successfully to resist the bacilli already located in them and to escape necrosis and ulceration.

Coming now to the contention that it is not likely that the bacilli in the intestinal contents multiply and produce their poison there to any extent, at the outset I desire to point out that the presence of specific bacilli in the intestinal contents is not essential to the theory of eliminative treatment. In their

entire absence the effect of purgatives would still be to carry out of the body the poison-laden bile and the serous exudate containing its quota of toxin. However, the objection does not appear to be well taken. There are many reasons that make it extremely likely that the specific bacilli do multiply and produce their poison in the intestinal contents themselves.

Presumptive evidence of their multiplication in the intestines is furnished by the fact that the infection is carried by the intestinal contents. The simultaneous infection of several feet of the intestinal mucosa I have before advanced as a reason for believing in a previous multiplication in the intestinal contents.[12]

There is much difference of opinion among bacteriologists concerning the identification of typhoid bacilli in the intestinal contents. The very close resemblance to the colon bacillus is the great difficulty. As bearing directly on this question, I quote the following from the recent Croonian lectures by Prof. Sydney Martin.[13] "It has been said that inasmuch as the bacillus is not constantly found in the motions and is found in the urine, that there are not many bacilli in the intestine. There is nothing whatever in this argument. We can readily see that the bacillus might not be discharged in the fæces in sufficient numbers to be easily found. Moreover, if there is a great increase in the number of bacillus coli in the intestinal tract, not only is there great difficulty in finding the typhoid bacillus in the presence of large numbers of this micro-ôrganism, but the more vigorous bacillus coli might actually beat out of the field the less vigorous typhoid bacillus."

One must also not lose sight of the fact that much of the toxæmia is, as I have before argued,[14] in all probability due to the products of associated bacilli and to decomposition in the intestine.

In the case of the bacillus coli the probability is exceedingly strong that it plays a very considerable part in the production of the symptoms seen in typhoid. In a former paper I drew attention to the fact that the damaged intestinal wall opened the way for the migration of the colon bacillus from the intestine.[15]

The recent experiment of Sydney Martin[16] would seem to have definitely settled the point. He extracted colon bacilli from the spleen of a patient with typhoid fever, and found that their virulence was much increased over that of colon bacilli from the normal intestine. He assumes, also, that the colon bacillus had been carried from the intestinal canal.

We have in this experiment an actual demonstration of the correctness of the view held by many that the bacillus coli becomes increased in virulence when associated with the typhoid bacillus. It is also confirmatory of the belief that the injury done to the intestinal wall by the specific bacillus opens the way for the colon bacilli. These facts being borne in mind, it is surely not difficult to appreciate the advantage of keeping the intestine as free as possible from bacilli of all kinds, even if one were to grant, in spite of evidence to the contrary, that the typhoid bacilli do not multiply and produce their poison to any extent in the intestinal contents themselves.

I believe, too, that in preventing decomposition and bacterial accumulation in the intestines, the liability to those bacterial invasions of the weakened body in the late stage of the disease, commonly spoken of as "terminal infections," is greatly lessened. Undoubtedly the invading bacilli in the vast majority of these cases come from the intestine.

The constant effort to facilitate elimination and keep the toxæmia at the lowest point throughout the disease of course contributes in lessening this liability, owing to the fact that nutrition is less interfered with, and consequently the tissues maintain a higher quality of resistance.

In advancing the theory of eliminative treatment in typhoid, I have always adhered to the view that much of the toxæmia and many of the symptoms were due to the associated bacteria;[17] that there was, in other words, a mixed infection, if not primarily, at all events as a later development.

Regarding the experience of those who have adopted the eliminative plan of treatment, I am not disposed to accept what Dr. Osler asserts is their verdict, namely, that the mortality is not materially increased over that of the symptomatic plan. Their experience, I believe, and I have had many communications and many opportunities for discussion, goes to show that the adoption of the eliminative plan lowers the mortality in a remarkable degree. More than that, it lessens the severity of the symptoms and the duration of the fever. Indeed, many of the symptoms wholly disappear under this form of treatment.

I might instance the record of the Toronto General Hospital, although not all the cases were treated on this plan. However, the vast majority were treated either on the eliminative plan or by means of calomel and salines or other purgatives freely and frequently given. No selection of any kind was made and there was no attempt to make a record. One of the deaths occurred on the day the patient was admitted. No cases are excluded from the list. In the four years from 1893 to 1897 there were 563 cases, with 37 deaths, 6.57 per cent. mortality.

In the paper above referred to and on a former occasion, Osler, in referring to this plan of treatment, directs attention to the fact that La Roque, of Paris, advocated the use of purgatives in the treatment of typhoid cases in 1849, and is inclined to make it appear that the plan of treatment advanced by me is simply a revival of an old treatment. While I would not for a moment detract from whatever credit is due M. La Roque, yet I altogether fail to see how the empirical giving of purgatives in utter ignorance of the nature of the disease, at a time when no distinction was made between typhus and typhoid, and when the existence of bacteria was not even guessed at, can be made to appear identical with the eliminative plan advanced by me and based on the relatively clear light which the most recent facts of physiology and bacteriology have thrown upon the pathology of typhoid fever and upon the nature of bacterial processes in the body generally.

Reference is also made to what Professor Osler somewhat contemptuously calls the "gunshot" Woodbridge tablet. Examination into this method of treatment shows it to be simply an adaptation of the eliminative and antiseptic plan. At first the use of the calomel and antiseptic tablets was unaccompanied by any theory as to their action, but gradually the theory advanced by me, setting forth the eliminative and antiseptic plan of treatment, has been utilized, until recently the title chosen by me for my first communication on the subject has been appropriated, and one reads of "the eliminative and antiseptic treatment of Woodbridge."

Why simply combining a purgative with antiseptics in the form of a tablet, after the theory and principles involved have been fully set forth, should be considered a special form of treatment, passes comprehension. One cannot easily see, either, the advantage of a scheme which makes the attending physician simply an automaton.

Surely the choice of purgatives and antiseptics and the apportioning of them may with much greater advantage be left in the hands of the physician at the patient's bedside. Having a clear conception first of what he hopes to accomplish by them, he may then

make his selection and arrange dosage from day to day, according to the requirements of the case, in a rational manner.

In conclusion I may be permitted to point out that my contention in the article in which the theory of the eliminative and antiseptic plan of treatment was first set forth, in the *Canadian Practitioner* of April, 1893, was that the profession had, to use Osler's words, been too fearful of the danger of purgatives in typhoid fever, that the danger had practically no real existence, and that the imaginary danger most effectually barred the way to treatment which appeared to be the logical outcome of the clearer ideas concerning the nature of typhoid fever and in a general way of bacterial processes.

So unorthodox a contention met with widespread opposition, as might have been expected, because it was diametrically opposed to the teaching found in every text-book on medicine. However, since that time opposition in this country has gradually disappeared, until now we have this virtual acknowledgment of the correctness of the position I then took, coming from one of its most pronounced and most powerful opponents.

TRAUMA A CAUSE OF APPENDICITIS.

By WILLIAM B. SMALL, M.D.,

LEWISTON, ME.,

ASSISTANT IN SURGERY, CENTRAL MAINE GENERAL HOSPITAL.

On every hand we hear the query, "Why is there so much more appendicitis to-day than ever before?" Answers to this query are not very satisfactory. The medical profession takes credit to itself, and says, "We are much better able to make the diagnosis." But this hardly explains the half of the increase. It would take many times all the cases of peritonitis, perityphlitis, and paratyphlitis of twenty years ago to equal in number the cases of appendicitis of to-day. To find a satisfactory explanation of this increase in all its phases we must study more carefully the causes which lead to the inflammatory involvement of the appendix. In this way alone can the true solution of the question be reached.

The idea is gaining ground that the appendix is anatomically a glandular organ. Among foreign writers especially it seems to be considered somewhat analogous to the tonsils. Its disorders then would be like those of the tonsillar bodies—follicular, mucous, submucous, infectious, exudative, and ulcerative. To continue the analogy, it is doubtless a fact that, as in the tonsils, the local inflammation of the appendix is caused by micro-organisms, specific or non-specific.

It has been demonstrated that the particular cause of the inflammatory process in the appendix is the bacillus coli communis, though in a certain proportion of cases other micro-organisms, especially the staphylococcus pyogenes and streptococcus, are also found.

These germs may gain admittance to the appendix in the intestinal fluids, or more frequently with irritating fæcal matter in hard egg-shaped concretions of various sizes, introduced into the appendix from the cæcum by force of pressure. Foreign bodies (cherry stones, orange seeds, spicules of bone) are more rarely found in the lumen of the appendix, but all come from the same source (the cæcum) and in the same way, by being forced in. The irritation of the mucous membrane by these hard substances furnishes a foothold for the bacilli—staphylococci and streptococci—to multiply and perform their destructive work.

Why this condition should occur so much more frequently during recent years is not uniformly explained. We are told by some observers that the valve over the end of the appendix is defective. The existence of this valve is not universally admitted, much less its defective condition.

Some assert that the existence of intestinal catarrhal conditions in connection with the grippe is responsible for the large increase of appendicitis in the past few years. This point seems to be proved from figures quoted by Goluboff,[1] who states that in Moscow, during the spring, summer, and autumn of 1896, the number of cases increased to four or five times the average of the past ten years.

While this explanation seems the most satisfactory one that has come to my notice as far as the general increased prevalence of the disease is concerned, there is another point in this connection which demands further attention.

All who have studied the disease agree that the majority of cases are found in young adult males, a majority so large that they furnish seventy-five to eighty per cent. of all cases. About seventy-five per cent. of all patients are under thirty years of age. These figures are significant. Occurring in other diseases, surgical or medical, we have been taught to explain such prevalence by the fact of greater liability to the predisposing cause or more frequent exposure to the exciting cause. Clinical observation and experience show this theory to be well sustained. Does it apply as well to appendicitis?

The fact that some part of the contents of the bowel nearly always furnishes the exciting cause of appendicitis makes it but logical to seek the explanation why this material should be forced from the colon into the appendix. It is reasonable to suppose that muscular contraction will produce this result. But why should the cæcum undergo such contractions more often in the male than in the female? I believe there is a sufficient explanation behind all this. I believe the true cause of the greater percentage of occurrence in young men is found in their more frequent exposure to accidental injuries and strains, and to the strong contractions of the abdominal muscles necessary in their work, thus, in either case, producing great pressure on the contents of the bowels; of this compression the cæcum receives its full share, being on the right, and usually more active side of the body. This result is but natural, and is in accordance with the principle I have stated, which is well recognized in other medical and surgical subjects.

That such a cause is sometimes hard to trace is but a natural result from the time required for the production of local inflammation from the concretion, and for the development of the germs in sufficient

[1] Berliner klinische Wochenschrift, January 4, 1897.

quantity to produce an effect so great as to be recognized by symptoms. This interval will be apparent to you as you listen to the cases I will report.

In the literature of appendicitis traumatism is mentioned as an infrequent cause. I have been able to find but one case reported with this the only cause. This case was that of a boy of sixteen years, who was struck in the right iliac region by the handle of a pushcart. A distinct tumor in that region occurred; the tenderness was most acute over McBurney's point. The tip of the appendix was found gangrenous. This case was reported by Dr. W. S. Coley in the MEDICAL RECORD of February 15, 1896.

Much like this, however, is a case reported in the New York *Medical Journal* of October 24, 1896, by Dr. D. C. Moriarta, in which a pin was found in the appendix, having been there a year without producing trouble, until inflammation was lighted up by a blow.

Rutherford Morrison, in the *Edinburgh Medical Journal*, March, April, and May, 1897, concludes that a strain may apparently originate an attack, a point which he considers of medico-legal importance.

My attention was first called to traumatism as a cause of appendicitis in the autumn of 1894, when I was called to see a young man unmistakably suffering from appendicitis. Two days before, while attempting to pry up a heavy stone by bringing his weight down on an iron bar while holding it between his thighs with his hands, he lost his hold and the bar struck him a heavy blow in the right iliac region. During the two weeks following he passed through the usual phases of an attack of appendicitis, with tenderness at McBurney's point, large, plainly defined tumor in the right iliac region, etc. He recovered without operation and has had no second attack.

The second case that was plainly of such origin was that of a boy, nine years old. This case occurred in November, 1896. I saw the boy very early in the attack, but could not get from him any history of injury till my second or third visit, when he admitted that the pain first came on while he was playing and pushing a heavy two-horse dump cart by the tongue. The cart was hard to move, so he put the end of the cart tongue against his "belly," his hands farther up toward the cart, and pushed "hard." This occurred about twenty-four hours before my first visit. The abdomen was opened on the fifth day and a quantity of pus found. The appendix sloughed away. The child recovered fully.

The third instance of traumatic origin was in a young man, a carpenter. This occurred in June, 1897. In lifting boards from a pile and handing them up to a man above him on the second-floor staging, in order to expedite matters he used his groin as a fulcrum, applying the power by taking hold with his hands, two feet or so from the end in his groin, and lifting. This brought a great pressure across his bowels upward and toward his backbone. In less than forty-eight hours the symptoms of appendicitis began. The course of the disease was typical, and fair recovery was made without operation.

This patient fell under my care because his own physician was ill and unable to attend him. Some three months later a second attack occurred under the care of that physician, by whom appendectomy was promptly performed. The genuineness of the first attack was then proved in the thickening of the omentum and the adhesions of the neighboring parts. Pus was also found. His recovery was rapid and uninterrupted by any adverse symptoms.

I have reported to you those cases which have come under my own care in which traumatism as a cause was plain. Several others in this vicinity have come to my knowledge, histories of some of which I will outline.

Dr. J. A. Donovan, of Lewiston, has given me the details of a case of appendicitis occurring several years ago, in which a boy, about ten years of age, was thrown down and one of his playmates jumped on his abdomen. The immediate pain was great, but soon subsided sufficiently for him to get home. Three days later the doctor was called and found a tumor in the central pelvic region, which was opened through the rectum. Pus and two enteroliths escaped, the cavity was washed and drained, and the boy recovered.

Dr. John Sturgis, of Auburn, relates a case in a boy of eleven years, who was kicked in the abdomen by a horse on Wednesday or Thursdeay. On the following Sunday appendicitis developed. The abdomen was opened and the diagnosis confirmed. The patient afterward died of general peritonitis.

Dr. F. L. Dixon, of Lewiston, details a case in a man, twenty-seven years old, who fell through a trapdoor seven or eight feet into a cellar. He complained of injury to his right side, but was not sick enough to send for a physician. This feeling of discomfort continued for two or three weeks, when symptoms of appendicitis appeared. Dr. Dixon was called on Friday. The diagnosis was made on Saturday. Sunday night the patient suffered severe pain and became collapsed. Incision made on Monday showed the abdomen full of free pus. Two enteroliths were found in the appendix and a gangrenous portion between them. Death occurred in a few hours.

The same physician, in January, 1897, operated on a man, thirty years of age, in an advanced stage of appendicitis. Old adhesions were found, in keeping with the history of repeated attacks. The man died a short time after the operation. Though no history of violence was obtainable at that time, several months later the following facts were related by the patient's mother: In the summer of 1896, when on a small island, the patient, in jumping from one shore to another, felt a sudden sharp pain in the right iliac region, so sharp as to make him lie down. He was a long time in getting home, having to lie down often to rest. He was about the house for several days before he was able to return to his work. Between that time and his last illness he suffered from three or four attacks.

Dr. Donovan also reports a case in a boy of nine years of age, who was jumping from a height to the ground. In three or four days appendicitis developed. The appendix was removed and recovery followed.

Dr. John Sturgis reports a case in a girl, seven years old, who fell from a swing, and developed appendicitis three days after the accident. The case was treated medically and recovered.

He also reports a case in a man, twenty-two years old, who was leading a frisking and jumping horse. In trying to hold him the man strained his side. This was on Friday. On Monday afternoon severe pain began; tumefaction and the other usual signs of appendicitis followed in rapid succession. No surgical interference was allowed. Recovery seemed perfect, and the man is now in the United States navy.

The following cases are of a slightly different class and show the effects of occupation:

Dr. Donovan reports a case (seen by him in consultation) of competitive wood-sawing between two young men. The trial ended on Saturday night, and on the following Monday one of the competitors developed a well-marked case of appendicitis. The case was treated medically and the patient successfully passed through a second attack.

Dr. B. F. Sturgis, of Auburn, reports a case in a man who did a hard day's work in the hay field on Saturday, pitching and raking the hay. The next

night it was possible to make a diagnosis of appendicitis.

Dr. Sprague, of Turner, reports a case of a boy of sixteen, unused to labor, who shovelled sawdust all day. Pain began within twenty-four hours, and the usual symptoms of appendicitis followed. The abdomen was opened on the tenth day. Recovery was perfect, though the wound healed slowly. It may be interesting to note that just before this boy was operated on he told some of the physicians present that his first pain was very severe, and was felt immediately after "skipping" a stone along the surface of the water on the day of his labor with the sawdust.

The same observer reports a case in a tailor who worked hard throwing wood into a shed. Another in a man who had done a severe day's work sawing ice.

Reports of such cases can be multiplied indefinitely, but I have mentioned enough to illustrate the several classes of accidents causing appendicitis, namely, external violence, direct and indirect, sudden strains, and repeated strong contractions of the abdominal muscles.

It may not be always easy to trace the relation of the cause, traumatism or strain, to the effect, appendicitis. But from my experience I believe that such a cause exists in a far greater proportion of cases than we imagine, till we search carefully for it. The relative percentage of the occurrence of appendicitis can be logically explained, to my mind, in no other way.

This explanation brings the subject into prominence from a medico-legal standpoint. Some of these cases are plainly the direct result of external violence, and I believe accident insurance companies, or corporations and individuals responsible for the occurrence of the accident, are as plainly liable for them as for a broken limb. Other cases are more obscure. But of all the attacks of appendicitis of purely accidental origin which I have cited, there are none in which the liability would be less plain than in the case of pulmonary disease from injury to the shoulder, which forms the subject of an editorial in the *Journal of the American Medical Association* for March 19, 1898. This case has lately been on trial in one of the large cities of the union. I will quote from that editorial.

"In the case which we have referred to, a man, by occupation a grinder, and suffering from the early manifestations of 'grinder's disease,' of the lungs, was thrown with considerable violence from the platform of a street car, and struck upon his right shoulder and chest with so much force as seriously to bruise the tissues over the ribs in the axillary line. Within the course of a week or two it was noticed that the man's health had become very much impaired. Shrortly afterward evidences of pulmonary disease became manifest, and thirty-five days after the accident the man died. At the post-mortem examination no evidence of external injury was manifest, the ecchymosis resulting from the accident having been absorbed. One lung was found to be almost entirely consolidated and the other partially so. Scattered through both were a number of large deposits of fine metallic particles, derived from the emery wheels and the steel which he had been accustomed to grind.

"Suit was brought by the administratrix of his estate, it being claimed that his ill health and death within a short time of the accident was the result of the accident. It was admitted by the railroad company that the accident had occurred, and that, so far as the accident itself was concerned, it was responsible. The question which rested on the medical experts for decision was whether the pulmonary disease which eventually resulted in the man's death could be attributed to the accident, and the testimony was such that immediately after it was heard the railroad company sought a settlement, which was granted. It was testified that severe injury to the chest might very readily so impair the vitality of the lung as to cause the rapid spread of disease already existing, but very mild in character, or to render the lung peculiarly susceptible to any infection to which it might be exposed. If the consolidation of the lung, which finally resulted in the man's death, was due to a tuberculous process, then it would be very easy to understand how a violent injury to the chest wall might so disorganize the inflammatory exudations, which had been thrown out around tuberculous and metallic deposits, that they might be broken down, thereby making open the pathways for general infection. On the other hand, it was possible that the micro-organism of pneumonia, always present in the upper respiratory passages of man, might find a ready soil for its propagation.

"This testimony is indorsed by a large amount of literature which has been accumulating during the last few years, particularly since accident insurance has become popular."

A very valuable paper bearing directly on this subject of localized infectious diseases as a sequence of slight injuries, has been written by Dr. McDill, of Milwaukee, in association with Mr. Van Alstine, of the Chicago, Milwaukee, and St. Paul Railway, and published in the *Railway Surgeon* of January 11, 1898. This paper considers mainly tuberculous and pneumonic infection. The conclusion is drawn by them, "that when negligence causes this injury and the injury proximately causes diesase, both the injury and the disease are elements of damage in legal action."

It is well for us to bear in mind that small injuries may give rise to grave diseases, and also that, this fact being known to the public, "strained relations" between cause and effect will be more frequent than ever before. Careful notes of all such cases should be kept, so that if suit be brought the full history from beginning to end may be given.

We may, I think, reasonably draw these conclusions:

1. That general prevalence of catarrhal conditions of the bowels, perhaps as an accompaniment or result of the grippe, is responsible for a large part of the general increase in prevalence of appendicitis.

2. That accidental injuries, strains, and work demanding strong contraction of the abdominal muscles may be held accountable for the greater prevalence of the disease in males.

3. That such injuries and strains act by forcing material, loaded with the bacteria which produce appendicitis, from the cæcum into the vermiform appendix.

4. That in consequence of the irritation of such material or from some other cause, these germs here find a favorable soil for their multiplication and development.

5. That in common with other germ diseases a time of incubation must elapse (for the multiplication of these germs) before symptoms sufficiently marked to prove characteristic of appendicitis can appear.

6. That the disease is of growing medico-legal importance, as many cases are of traumatic origin, and may therefore give rise to proper suits for damage or valid claims against accident insurance companies.

Microcephalus.—Nothing perhaps exhibits the enthusiasm of modern surgery more than these attempts to coax an undeveloped idiotic brain to execute the functions of intelligence.—AGNEW.

ADENO-CARCINOMA OF THE NOSE, WITH REPORT OF A CASE.*

By MAX THORNER, A.M., M.D.,

PROFESSOR OF CLINICAL LARYNGOLOGY AND OTOLOGY, CINCINNATI COLLEGE OF MEDICINE AND SURGERY, LARYNGOLOGIST AND OTOLOGIST TO THE CINCINNATI HOSPITAL, ETC., CINCINNATI, OHIO.

A GREAT difference of opinion exists among writers regarding the frequency of adenoma and carcinoma of the nose. Adenoma of the nose is not mentioned in the text-books of Morell Mackenzie,[1] E. Fletcher Ingals,[2] F. De Havilland Hall,[3] Moldenhauer,[4] Carl Seiler,[5] Schech,[6] Voltolini,[7] Lennox Browne,[8] Réthi,[9] Zarniko,[10] Flatau,[11] and Scheff.[12] All of these authors consider carcinoma of the nose a rare occurrence. Seifert and Kahn[13] do not picture a case of adenoma or adeno-carcinoma of the nose. What they reproduce on plate 16 of their atlas is an adeno-carcinoma of the *ala nasi*, and not of the nasal mucous membrane. Bosworth [14] is of the opinion that unmixed adenoma does not occur in the nasal cavity, and that when glandular tissue is met with in a neoplasm, it is purely adventitious, as in adeno-sarcoma, adeno-carcinoma, adeno-fibroma, etc. He also considers carcinoma of the nose as one of the rarest conditions, although he does not accept the assertion of Cornil and Ranvier, made as late as 1869, in their "Manuel d'Histologie Pathologique," that there is no well-authenticated case of primary carcinoma of the nose.[15] Moritz Schmidt is apparently of the opinion that adenomata of the nose are rare, and he does not mention the occurrence of adeno-carcinoma.[16] However, he mentions that carcinoma in the anterior half of the nasal fossæ, according to his experience, does occur only as so-called transformation of "soft nasal polypi;" and lacking any more definite description it is not unlikely that these "soft, nasal polypi" of which he speaks, were histologically true adenomata. J. Solis-Cohen[17] mentions adenoma of the nasal cavity as unfrequent, and he says it may extend to the smallest anfractuosities of the nasal passages and adjacent sinuses. He does not consider carcinoma of the nasal passages as of common occurrence. P. McBride[18] questions whether true adenomata have occurred. Carcinoma, however, is according to him not infrequently met with. Moure[19] mentions adenoma and carcinoma of the nose, and considers both as of not common occurrence. Dreyfuss[20] considers carcinoma of the nose a very rare disease. He could up to the year 1892 collect only thirteen cases. Since then, however, a number of cases have been reported. Massei[21] mentions that according to Péan adenomata occur frequently in the nasal cavity, and that they are liable to cause death by meningitis. He does not mention adeno-carcinoma of the nose.

D. Newman describes a typical case of adeno-carcinoma of the nose, and says that two-thirds of carcinomatous tumors of the nose are epitheliomata and the remaining third adeno-carcinomata.[22]

Of late a few additional cases of adeno-carcinoma have been reported, although the histological details are in some cases missing, in others not definite enough to render the diagnosis absolutely reliable. These references may suffice to show that there is no unanimity of opinion regarding cases of this kind. The case which I had the opportunity of observing is the following:

F. P— —, aged forty-seven, farmer, was referred to me by Dr. V. T. Churchman, of Charleston, W. Va., September 16, 1895. During my temporary absence from the city he was examined by my assistant, Dr. J. H. Bindley, who made the following notes of the case: Father died of heart disease; cause of mother's death unknown. Is not aware of the occurrence of carcinoma or tuberculosis in his family. Had measles, mumps, influenza. Does not drink alcoholics; is a moderate smoker; denies venereal diseases.

About one year ago he noticed some obstruction in the left nasal cavity, which gradually increased until breathing through that side was absolutely impossible. At this time, about four months after he had commenced noticing the trouble, the doctor removed a large growth from the nose with the snare, after which breathing was again free for about one month. Then the same trouble appeared again.

He returned to his physician who removed another large portion of the growth. After this his breathing was free for about two weeks, when it became again impeded, until after another two weeks the left nasal cavity was again entirely closed. These operations had to be repeated in intervals of about one month, so that up to the present time eight operations had been performed. The operations were followed by moderate hemorrhage, but for most of the time were not very painful, and the patient suffered only from the obstruction. Has not lost weight. Appetite good.

He was referred by Dr. Bindley to my service at the City Hospital, where during my absence Dr. S. E. Allen took charge of him. The following is the condition which was noted upon his entrance into the hospital: Man of medium size; fairly well nourished; nothing abnormal to be seen about his face. Hearing in left ear diminished. The left side of the nose is entirely obstructed by a growth which extends from the vestibulum backward and fills completely the space between the choana and the Eustachian tube. Its color is grayish-red; its surface is slightly uneven, resembling somewhat a mass of cauliflower; is soft, and bleeds readily upon being touched with a probe. Its origin cannot be ascertained, but it appears to come from the middle meatus, which it completely obliterates. The septum is entirely free from any growth; no glands are enlarged.

A large piece, involving especially that portion which surrounded the orifice of the Eustachian tube, was removed by Dr. Allen with the cold wire snare. Hemorrhage rather abundant. The microscopic examination of the removed pieces showed that the growth was a typical adenoma.

On October 5th, about two and one-half weeks after this operation, the nose having become obstructed, I removed with the cold snare as much of the growth as I could. Another examination of the pieces removed confirmed the first diagnosis. Soon thereafter, the nose began to fill up again, and, it being entirely obstructed on October 22d, a thorough operation was done under chloroform anæsthesia, in which an enormous amount of the obstructing masses was removed from the nose and from the postnasal space with snares and curettes. Pieces varying in size from that of a filbert to that of a small walnut were removed. They all were friable. The hemorrhage was rather abundant. Left side of nose packed with iodoform gauze.

The patient was doing very well after the operation; no hemorrhage occurred after removal of the tampons.

On October 29th, one week after the operation, the growth was found to have returned again. The patient was now given to understand that there was no hope of removing all of the growth by intranasal procedure, and the advisability of a more radical procedure by temporary resection of the upper jaw was suggested to him. However, he refused any further operation and left the hospital.

Portions of the growth removed at this last operation were examined by Dr. Albert H. Freiberg, then microscopist of the hospital, who had the kindness to send me the following report:

"The surface of the growth is not papillary but

* Read at the annual meeting of the American Laryngological, Rhinological, and Otological Society at Pittsburg, May 11 and 12, 1898.

smooth. Lying in a well-developed stroma of young connective tissue, abounding in easily stained nuclei, is seen an enormous aggregation of tubuli of various conformation. Some of them are fairly straight, with lumina of small calibre; others convoluted in their course, and others still short with large dilated lumina, reminding one of cystic formation. Here and there is to be seen an atypical collection of epithelial cells without evident lumen.

"The tubuli are lined with a tall cylindrical epithelium, whose nucleus is large and very easily stained. I have been unable to detect anything like cilia on these epithelia. Taken altogether, the picture reminds one forcibly of the malignant adenoma of the uterus. I should call it malignant adenoma."

For the rest of the history of this case I am indebted to Dr. Churchman, of Charleston, in a neighboring village of which the patient lived. When he left Cincinnati, he was in fairly good health, but a few months thereafter he began to decline. The growth had to be removed every few weeks.

On April 25th, Dr. Churchman wrote that he had operated upon him eight or ten times since he left Cincinnati. But, whereas formerly these operations had been entirely painless, they were now so painful that he could hardly stand them. By this time his general health had become very bad. He had a sallow complexion; the septum and right side of the nose had become involved; the eyelids were œdematous. At this time he seemed to be willing to have any operation done. Meanwhile, Dr. C. had some of the masses removed on April 25th sent to the pathological laboratory of Johns Hopkins Hospital. The report was that it was a typical case of adenoma changing into an epithelioma. Dr. C. did not see the patient for one week. When he saw him again his nose was double its size and was purple; his eyes were very much swollen, protruding and bloodshot, and he was not able to swallow anything but soft and liquid food. The patient returned to his home, and Dr. C. did not see him any more. He died on June 12th, but Dr. C. did not hear of it until after he was buried, when he received the remainder of the history from the family physician. The patient grew rapidly worse; the growth broke through the walls of the nose at its bridge, from where severe hemorrhages took place; the left orbit was more and more involved, until two and one-half weeks before death the left eye was destroyed; and at the time of death the growth in the left orbit was about two and one-half inches in diameter, and bleeding all the time. There was absolutely no hearing for the last ten days or two weeks, and his mind was entirely destroyed for the last five or six days. Unfortunately Dr. C. did not hear of his death in time for a post-mortem.

We have to deal here with a case of malignant disease of the nose, the course of which, if the time of the commencement of the trouble was correctly stated by the patient, extended over a period of about two years. The only question that could arise, in my opinion, is, whether we had to deal with an adenoma that underwent carcinomatous change, or whether it was not a case in which there was present or developed later a carcinoma in addition to a benign tumor. Now, it is a fact that adenoma of the nose is looked upon by many as a benign tumor; so, for instance, by Moure,[19] but he says that the gravity of adenomata of the nose must be considered from the point that they have a manifest tendency to degenerate into carcinomata. It is true that many doubts have been raised against the probability of transformation of benign tumors into malignant ones, since Semon's collective investigation regarding the transformation of benign tumors of the larynx into malignant ones,[23] especially as a result of previous operations. Yet these investigations do not absolutely exclude the possibility of such an occurrence. Senn[24] says that he is convinced "not only that such a transformation is possible, but also that it takes place much more frequently than has heretofore been supposed." The same author says in another place:[25] "The liability of an adenoma to become transformed into a glandular carcinoma is perhaps greater than that of papilloma. In fact, according to Dr. J. Hamilton, carcinoma is preceded by an adenomatous stage. . . . The earliest evidences that such an occurrence has taken place are a more active multiplication of epithelial cells, and their migration through the basement membrane into the connective tissue outside the limits of the tumor. . . . "The transition into carcinoma is observed oftener than a resulting sarcoma." [26]

In reference to adenoma of the antrum of Highmore (and in this case there is nothing to show whether the tumor originated in the antrum or in the nose), Marshall[27] makes the statement that they "not infrequently manifest malignant tendencies, ending in adeno-carcinoma. The malignancy of this form of tumor is equal to that of the most malignant type of carcinoma." This tendency of some adenomata in mucous membranes to involve the submucosa and surrounding tissue is well known in some localities, especially in the stomach, the rectum, and, above all, in the uterus, in which latter place it is described by pathologists and gynæcologists as adenoma malignum.

Ziegler[28] says in this respect: "The clinical importance of adenomata is different according to their location, not only in regard to possible injury of vital organs, but also in reference to their behavior toward adjacent structures. . . . We can and should, therefore, differentiate an adenoma benignum from an adenoma malignum or destruens. . . . In an advanced stage of proliferation of these growths it is, indeed, the rule that part of the epithelial elements assumes the shape of dense cell conglomerations, and we are then in the habit no longer to call such a growth adenoma but an adenoma-carcinoma."

If, therefore, we are not inclined to believe that a primarily benign tumor, an adenoma, was transformed into a malignant growth, an adeno-carcinoma, we may assume that there are certain forms of adenoma which from the start are of a malignant character, to be called adenoma malignum, although histologically they cannot at an early date be differentiated from a benign innocent tumor.

DIAGNOSIS OF ANEURISM OF THE THORACIC AORTA, ILLUSTRATED BY A CASE.

By PIUS RENN, M.D.,

HOUSE PHYSICIAN, GERMAN HOSPITAL, NEW YORK CITY.

The diagnosis of aneurism may be very easy or very difficult, and often it cannot be made at all. There is a triad of clinical symptoms, which, when present, makes the diagnosis simple and beyond any doubt. Where in the course of a vessel we find a pulsating tumor with its concomitant features—as murmurs, inequality of pulse in time and force, pressure symptoms, variable as to location, and, lastly, pain—the diagnosis of aneurism can be made almost with certainty. We have to exclude only a possible transmission of arterial pulse by way of a tumor, usually cancerous. The character of the pulsation, either expansive or vertical, settles that question at once. A second class of cases gives signs and symptoms of pressure, with or without pain, and necessitates a differential diagnosis as to the character of the tumor, aneurism or new growth. The presence of symptoms depends, as stated before, mainly upon the location of the aneurism. Those of the arteries of the extremities, and those of the ascending and usually also of the transverse thoracic aorta, since they are near to the surface, give early symptoms. Aneurism of the smaller and deep vessels, *i.e.*, of the brain, descending thoracic aorta, abdominal aorta, and its branches may long escape a definite diagnosis. A third class of cases takes an entirely latent course, with no symptoms whatever or with ill-defined ones; as, for instance, pain only of variable character; or they may not give any sign of their existence during life or up to the fatal termination by rupture. Those escape diagnosis altogether and are diagnosed only on the autopsy table. These statements hold good especially in cases of the smaller-sized aneurisms of the descending thoracic aorta. The deep-seated course of this vessel does not allow us to utilize our means of physical diagnosis before the sac reaches a size sufficient to erode vertebræ and ribs and appear on the chest wall. The adjoining tissues—pleura, lung, and œsophagus—stand encroachment by a tumor of moderate size in this region quite a long time before inflammatory reaction or too much pressure interferes with function. The absence of nerves, except the sufficiently protected intercostal nerves, gives immunity against pain and definite pressure symptoms for any length of time. It is true that positive proof of a tumor in the posterior mediastinum gives a great probability of the existence of an aneurism of the descending aorta, as specific gland enlargement or neoplasm in this region is rare (one to four). But this fact has only a relative value for diagnostic purposes. Therefore it is no wonder that the knowledge of aneurism of the descending thoracic aorta, according to Morgagni, reaches back only to Vesalius, 1557. His case presented a pulsating tumor. Aneurism was diagnosed and found at autopsy. Scarpa, in the beginning of this century, in his famous work, "Sul' Aneurisma," Pavia, 1804, describes and illustrates a case in detail, which was treated for rheumatism for a year, and terminated fatally by rupture into the subpleural tissue. The condition found at autopsy was somewhat strange. Bleeding took place into the subpleural tissue and from there through the diaphragmatic apertures into the abdominal cavity.

While through the researches of Morgagni, Scarpa, and others, the morbid anatomy of aneurism and its relation to other diseases have been fairly well explored, the diagnosis of aneurism still remains, under certain conditions, a matter of utmost difficulty; and in many cases of latent aneurism, especially of the descending thoracic aorta, it remains questionable up to the last moment. This fact is well borne out by a case which recently came under observation at the German Hospital, in the service of Dr. J. Adler.

Mr. P——, a salesman, forty-seven years old, was admitted to the German Hospital, April 17, 1898. The family history of the patient furnished no data of any importance. As a child he had measles. Sixteen years ago he acquired syphilis and suffered for some time from a specific pharyngitis. He always had been a heavy smoker and greatly addicted to alcoholic stimulants. His health was fairly good up to three months ago. At that time he complained of being easily tired and of some shortness of breath; he lost flesh gradually, on account of which he had to give up his work eight days before he entered the hospital. Two days before admission he had a severe chill and intense pain of indefinite location in his left chest. His formerly slight dyspnœa increased rapidly and he began to cough, raising some sputum, catarrhal in character. Appetite fair, bowels irregular, sleep disturbed, perspiration profuse.

The patient is rather emaciated, middle-sized man, very dyspnœic and cyanotic. The superficial veins of the face and upper extremities are dilated. The expression is anxious; the pupils are equally dilated. No œdema, no skin eruption, no luetic stigmata. Hacking cough; scarcely any expectoration. Pulse 116, full, strong, and regular, of moderate tension, equal on both sides in time and character. Radial artery neither tortuous nor atheromatous. Respiration, 30; temperature, 102° F.

Lungs. The respiratory movements on the left side are diminished, the intercostal spaces are wide and slightly bulging on inspiration. The circumference of the left chest exceeds that of the right by two centimetres. Vocal fremitus on the left side is wholly absent. Percussion in front and behind over the left lung shows absolute flatness over the right lung with hyperresonance. Over the left apex there are a few moist râles. At the level of the sixth rib, in the scapulary line, distant bronchial breathing, moist râles, and bronchophony are heard. Over the whole right lung the breathing is harsh and loud.

Heart. The right border is just inside the right mammillary line; the left border cannot be mapped out, as the heart dulness merges into lung flatness. The upper border reaches the level of the third rib, and the heart pulsation is perceptible just to the right of the sternum at the level of the right sixth costal cartilage. The mitral sounds are heard most distinctly at the right border of the sternum near its junction with the ensiform cartilage. In this region an indistinct murmur is heard, the character of which cannot be defined on account of the labored breathing. Over the aortic and pulmonary regions no murmurs are present. The second pulmonary sound is accentuated, the heart action strong and rhythmical and somewhat labored. Liver dulness in the mammillary line commences at the level of the sixth rib and reaches a line three fingers' breadth below the arch of the ribs. The stomach is dilated. The

spleen is not enlarged. The bladder reaches three fingers' breadth above the symphysis pubis.

As all the signs pointed to a large effusion into the left pleural cavity, a puncture was immediately made in the seventh intercostal space in the scapular line. After a few drachms of thick bloody liquid had been evacuated, the cannula became clogged and had to be withdrawn. A second puncture in the eighth intercostal space in the posterior axillary line furnished five hundred grams of bloody liquid. During this operation the cannula again became clogged. There was no cough or any other reaction during the puncture. The patient felt somewhat relieved. His breathing became easier, but the line of dulness was nowhere changed. Percussion over the apex seemed to give a rather higher pitch. He passed a fairly comfortable night and felt comparatively well during the following day. His pulse at 5 P.M. that day was 100; temperature, 101.8° F.; respiration, 30. At 8 P.M. an enema was given, after which the pulse rose to 120; respiration, 32. At 8:35 P.M. a chill set in, lasting ten minutes, accompanied by profuse perspiration. The face became pale and pinched, the pulse intermittent and weak. Camphor oil, ♏ xx., was given hypodermatically; but notwithstanding energetic stimulation the pulse did not recover. At 9 P.M. the pulse was no longer to be felt, and exitus lethalis occurred at 9:15 P.M.

The clinical aspect of the case led to the consideration of three possible conditions, viz.: tuberculous pleurisy, malignant neoplasm of the lung or pleura, rupture of an aneurism into the left pleural cavity. The first was ruled out by the character of the effusion, absence of tubercle bacilli in the sputum and effusion, and absence of other symptoms of tuberculosis. In favor of the second condition, at least to some extent, were the history of a gradual decline in health and the emaciation during last three months, and the peculiar cachectic look of the patient. In spite of these facts the diagnosis of malignant tumor was not accepted: first, on account of the microscopical examination of the fluid, which contained only red and white corpuscles without any other cellular elements; secondly, on account of the absence of bloody expectoration and the rapidity with which such a large effusion took place; lastly, because, with a malignant neoplasm, one naturally would expect more or less constant pain or definite pressure symptoms, both of which were absent. All these points being considered, the only rational diagnosis left was that of an aneurism of the descending thoracic aorta. This probable diagnosis was sustained by the subsequent development and the modus of the fatal determination.

Autopsy, made twelve hours after death, revealed the following conditions, as recorded in the autopsy journal of the German Hospital, April 20, 1898:

"Medium-sized male corpse; poorly nourished; dependent portions of body slightly discolored. Rigor mortis marked; no œdema; no defect of integument. Omentum majus poor in fat, dipping irregularly among and between the small intestines. No ascites. Colon transversum and descendens contracted. Stomach enormously distended and displaced downward, its lesser curvature at the level with the eighth rib. Vessels injected; areas of small capillary hemorrhages. Large curvature just below the umbilicus. Stomach contains small amount of remnants of food. Mucous membrane covered with greenish discolored, tough mucus. Liver in the mammillary line commences at the level of sixth rib and reaches a line three fingers' breadth below arch of ribs; surface rough and pale, edges sharp; on section nutmeg appearance. Spleen small and soft. Bladder distended; reaches half way up to the umbilicus and contains clear urine. Diaphragm of left side bulges far into the abdominal cavity. On cutting of the costal cartilages on the left side a gush of blood welled forth. Adhesions between pericardium and sternum, and a comparatively large amount of fat in the anterior mediastinum. The pericardium, exposed to its full extent, contains a normal amount of fluid.

Left border of heart in middle of sternum; right border just beyond right mammillary line; apex behind sternum at junction of sixth costal cartilage with sternum. Upper border at third rib. Sinus Valsalvæ silghtly dilated. Both ventricles hypertrophied. Right abo t one-sixth inch, left one inch thick; empty and strongly contracted. Valves intact, except slight thickenings on free border of mitral valve. Parts of ascending aorta and arcus aortæ extensively atheromatous. Right pleural cavity empty; strong adhesions over upper right lobe. Right lung, except for compensatory surface emphysema, normal. Left pleural cavity contains about one-half gallon of blood, clotted in the lower third and liquid in the upper two-thirds. Left lung completely compressed against spine, measuring five and one-half inches from above downward and two and one-half inches antero-posteriorly.

"All the thoracic viscera were now removed *in toto* by dissection of their attachments from the spine down to the diaphragm. The thoracic aorta was then slit open at its posterior aspect, and the following conditions were found: Below the level of the left bronchus, about opposite the fifth dorsal vertebra, is an opening into its anterior wall, a little to the left, of the size of a twenty-five-cent piece, leading into an aneurismal sac of about the size of a hen's egg. The neck of the same consists apparently of all three vascular coats. The remainder, lined by old coagula, is closely attached to left pleura and lung, to pericardium anteriorly, and to œsophagus to right and in front. This primary sac opens by a large slit-like aperture, now distended by old coagula, into the posterior mediastinum. Pericardium in front, lamina mediastinalis dextra to right, and lamina mediastinalis sinistra to left, forming as it were a secondary sac, entirely filled up with solid clots.

"From here the blood gained entrance into the left pleural cavity by an opening in its lower part, which could not be located with any exactness at the autopsy."

A close study of the specimen, together with the analysis of the clinical features of the case, shows that we had to deal with an aneurisma spurium of the descending thoracic aorta. We found atheromatous degenerations throughout the whole course of the thoracic and abdominal aorta, and on microscopical examination of the kidneys syphilitic obliterating endarteritis of the medium-sized arteries. It would appear that the first step in the formation of the aneurism was not a gradual dilatation of the coats of the vessel, but rather a complete and sharply defined perforation of the vascular wall at a place where total atheromtaous and fatty degeneration of the coats paved the way. While this process was going on, adhesions, no doubt, were already in process of formation, and led to the matting together of the adventitia with the pleura and lung. When, therefore, perforation took place, aided undoubtedly by the action of the hypertrophied heart and the effects of severe physical labor and abuse of alcoholic stimulants, the escaping blood was retained in the preformed adhesions, which took upon themselves the office of an aneurismal sac. The same factors still at work led later on to the rupture of this primary sac at some *locus minoris resistentiæ*, allowing the blood to fill the posterior mediastinum. That accident may have taken place at any time during the last three months. Dur-

ing all that time life was in jeopardy, clotting of blood and formation of new adhesions counteracting the dangerous tendency. At the time of the first chill bleeding into the open pleural cavity may have started, leading to an extensive hæmothorax, compression of the lung, and acute anæmia. A slight exertion was now sufficient to widen the tear and empty the heart chambers so completely as to lead of necessity to a fatal termination.

The difficulties of arriving at a positive diagnosis before rupture are obvious. All the cardinal symptoms of aneurism were absent. Pain was not a prominent feature in the case, up to the time of rupture, and then was indefinitely located. The location of the aneurism did not give the advantage of applying the resources of physical diagnosis. The comparatively small-sized tumor could encroach only upon the œsophagus, but dysphagia was not complained of, although in the specimen beginning compression of the lumen of the œsophagus is very evident. The positive symptoms, as observed at the time of admission or recorded in the history, pointed rather toward a new growth. Even the urgent symptoms after rupture gave positive proof only of a large effusion into the left pleural cavity and led at first not even to the assumption of internal hemorrhage, as pleurisy with a rapid effusion was not improbable. Only puncture of the pleural cavity, which furnished pure blood, led to a correct diagnosis. The abnormal position of the heart was probably influenced by the aneurism pushing from behind, but the large pleuritic exudate or a hæmothorax would account for it just as well. It is difficult to say how long the condition existed; it gave symptoms, according to our records, over a period of not more than three months. As to etiology, the modern view, that lues and alcoholism are the conditions *par excellence* leading to endarteritis and aneurism, is sustained.

THE NEURASTHENIC SYMPTOMS OF GASTRO-INTESTINAL DISEASE.[1]

By G. W. McCASKEY, A.M., M.D.,

PROFESSOR OF NERVOUS DISEASES AND CLINICAL MEDICINE, FT. WAYNE COLLEGE OF MEDICINE, FT. WAYNE, IND.

In the course of my professional work certain facts occasionally present themselves to me with unusual force. One of these has recently been the remarkably large proportion of patients who have manifested, more or less conspicuously, the so-called neurasthenic group of symptoms. Possibly this should not be a matter for surprise when we consider the close and intricate relationship existing between the nervous system and every organ and tissue of the body. In fact, the more closely this relationship is scrutinized, the less will be the surprise at the widespread distribution of this group of symptoms. Nevertheless, the fact is one of far-reaching importance, not only because of the large number of cases in which it becomes a living issue, but because of the danger of resting the diagnosis with neurasthenia without going beyond this to ultimate causes, which may be either primary or contributory in character, but which in either event will demand full recognition in the highest interest of the patient. In saying that these cases present the neurasthenic group of symptoms I do not wish to be understood to assert that they are all cases of primary neurasthenia. The well-recognized syndrome known as neurasthenia may be briefly defined as a chronic fatigue neurosis, in which the nervous system is in a condition of irritable weakness. The symptoms are such as should be expected from such a pathology, the exact clinical picture, sufficiently protean in its details, depending upon a large variety of circumstances, among which may be mentioned the personality and occupation of the patient, and the part of the nervous system which suffers the most. The sensory symptoms are usually dominant, and they find their clearest explanation when analyzed from this point of view. Here, as elsewhere, pathology is only perverted physiology; and in the fatigue sensations of health we find in milder and evanescent forms the counterpart of those presented in neurasthenia. "I am so tired that I ache," is a familiar experience and a familiar expression. And if the man who has made a consummate fool of himself by making a so-called century bicycle run—one hundred miles in one day—would give us a critical analysis of his subjective symptoms, and we should then imagine that they are permanent, or reproduced by trifling causes, as I have observed that they sometimes are, we should have a clinical picture of one form of neurasthenia. The multiform pains of neurasthenia are the intensified phenomena of a chronic condition, not perhaps absolutely parallel, but similar in a high degree to that of acute fatigue. Of course this only carries us a step farther back in our search for truth, and still leaves unanswered the question, "To what are all fatigue sensations due?"

The answer is not simple. They are undoubtedly complex in their origin. They are partly toxæmic, the severe and prolonged functional activity of the nervo-muscular apparatus resulting in an increased formation of leucomains, and the pouring into the blood of the products of retrogressive metabolism, especially the salts of potassium. Elimination is unequal to the task, and toxæmic pains and other phenomena follow the temporary accumulation. Then there are the local circulatory changes, which are of supreme importance. In both acute and chronic fatigue these play an important rôle in the production of sensory disturbances. Lastly, but really most important, come the histochemical changes of nerve and muscle cells. This is largely an unwritten chapter; but enough is known to justify a positive assumption of its importance. We may confidently assert that functional activity of a nerve cell produces transient structural changes within that cell. These changes constitute the real morbid anatomy of neurasthenia, so far as the primary condition is concerned.

Charcot divides the symptoms of neurasthenia into two groups, including in the first group those which are primary or essential, and in the second those which are secondary or incidental. In the former he places neurasthenic headache, sleep disturbances, rachialgia, and spinal hyperæsthesia, muscular weakness, disturbances of digestion, sexual and mental disturbances; and in the latter vertigo, special sense, respiratory, circulatory, and secretory disturbances, general sensory disturbance, etc.

Dercum prefers to erect two distinct groups of neurasthenia, one of which he calls neurasthenia essentialis, and the other neurasthenia symptomatica—terms which are self-explanatory. This distinction is clearly a valid one from an etiologic point of view, whether there is a corresponding pathologic distinction or not.

The cases that I have in mind in presenting this subject would be included in the second group. In many of these cases of neurasthenia symptomatica the neurasthenic symptoms are so predominant as to mask more or less completely the primary gastro-intestinal disease. I have had many such cases under observation. As illustrative of this group I will briefly report the following case:

Mrs. B——, aged twenty-five years, consulted me May 24, 1898, complaining of extreme nervousness

[1] Read before the Northern Tri-State Medical Society, at Elkhart, Ind., July 19, 1898.

and general debility, "rheumatic" pains in the shoulders of several weeks' duration. There were also severe general pains in the muscles throughout the limbs, considerable drowsiness, and headache on slight exertion or excitement; the appetite was fair and there was no distress in either stomach or bowels; there had been considerable palpitation of the heart at times. The patient had had what she called "nervous prostration" four years ago, lasting about six months, the symptoms of which were similar to those she complained of now. Urinalysis was negative throughout. Upon closely questioning the patient I found that she had occasional eructations of gas from the stomach, and thinking that the digestion might be at fault I persuaded her to let me introduce the stomach tube.

The first examination consisted in introducing the tube in the morning on a fasting stomach, no fluid or food having been taken since the previous evening. About ten cubic centimetres of a faintly opalescent fluid was obtained, of acid reaction, the acidity being equal to about fifteen degrees. Examination showed that it contained no free HCl, and no acetic or butyric acid. The acidity was due principally to lactic acid. Microscopically the fluid was found to be loaded with lymphoid and epithelial cells and bacteria.

The Ewald test breakfast was administered, showing briefly total acidity of fifty degrees, with twenty degrees of free HCl, equal to about 0.7 per cent., very faint biuret reaction, and very imperfect digestion of starch.

A diagnosis of chronic gastritis and symptomatic neurasthenia was made, and suitable treatment was instituted, with the result of relieving the patient of all symptoms in about four weeks. The patient is now apparently well, free from all neurasthenic symptoms, and able to do her own housework with ease. This case represents a type of gastric disease, in which, for some reason, the local sensory symptoms of the stomach disorder are almost entirely wanting, and the local disease is more or less completely masked by the secondary toxæmic and neurasthenic phenomena for which the patient seeks advice, and which cannot be successfully treated without removing the primary causal condition. More commonly, however, the gastric symptoms are not so latent as in this case. Intestinal symptoms are much more likely to be overlooked. For instance, a gentleman consulted me a fortnight or more ago, complaining of extreme nervousness, insomnia, marked general debility, persistent headache, and general pains. Interrogation of all the principal organs failed to reveal structural changes. The urinalysis was negative with one most important exception, viz., marked indicanuria. I suggested intestinal disease, but he protested against its possibility, declaring that his bowels moved with clock-like regularity, that the movements were normally soft, free, and of natural color, and that he was absolutely free from intestinal or abdominal symptoms. I insisted that in my experience indicanuria practically always meant intestinal disease, and he yielded to an examination. An intense colonic infection was found, mostly bacterial, in which a chromogenic bacterium, giving some of the colon contents the macroscopic appearance of blood, predominated. Daily treatment was at once instituted; the symptoms began to yield in two days, and the patient is now well on his way toward recovery.

I wish here to say a word about the diagnosis of intestinal disease. Reliable results are impossible by the slipshod methods commonly in vogue. I have had placed in one of my office rooms a closet, of the variety which retains the excrements in a shallow porcelain reservoir until defecation is completed. An adjustable electric light is so arranged that it can be placed within the basin, and the stool can be carefully inspected by good illumination. Much information is obtained in this manner. Certain portions are then selected and placed in a suitable container, labelled, and removed at once to the laboratory. I formerly used beakers, but now use jelly glasses with tin covers. They are cheaper, less fragile, and can be more lightly covered. The matter is subjected to careful microscopical study and this seldom fails to place a case in a clearer light. But this is not all. The patient is taken into a room adjoining the closet, placed upon a table on an inclined plane, a colon tube is introduced, and a quart or more of water is passed well up into the colon. The water is then allowed to flow out into a glass jar, and in many cases numerous membranous masses as large as one's finger will be found, even when none could be seen by the naked eye in the freshly voided fæces. Perhaps only a slight cloudiness of the water will be seen. In this event the water is placed, either before or after decantation, in a centrifuge, and microscopic evidence of disease is frequently found in this way. I am constrained to make this digression because of my belief that, while stomach examinations are more completely carried out, intestinal examinations are quite generally neglected, although when thoroughly and scientifically conducted they furnish the key to many otherwise inexplicable cases.

The neurasthenic symptoms commonly present in these cases will be found to vary greatly. I have no data at hand except those of personal observation; these I will attempt to summarize in a very general way, without any pretension to detailed analysis or completeness. General fatigue sensations are quite common in my experience. These are sometimes very mild in character, limited perchance to a more or less marked feeling of lassitude, with an inordinate sense of fatigue on slight exertion. In severer cases the various grades of neurasthenic pains are manifested sometimes in very aggravated forms. In some cases these pains overshadow everything else and rack the patient's nervous system day and night, with disastrous results upon both the nerves and the general nutrition. I have such a case under observation and treatment at the present time. Such pains are, perhaps, mostly due to a pure toxæmia; but the patients are usually neurasthenic, or, if not, rapidly become so.

Next to these may be mentioned the head symptoms of various kinds. These may consist of pain or pressure sensations of diverse forms, and are probably due to circulatory changes in the meninges or elsewhere. Incapacity for sustained mental effort may be manifested in varying degrees. This, like the motor weakness, may be the result of vasomotor disturbances of the cerebral cortex, histochemical changes of the cortical cells, or the direct action of toxins.

In one of my severe cases of chronic gastritis a typical migraine of years' duration, which had kept the patient in bed from one-third to one-half of her time, was completely cured in two weeks of stomach treatment. Both the patient and myself supposed that the migraine antedated the gastritis, and our surprise and gratification at its complete disappearance were mutual. More than two years have elapsed without any recurrence of either migraine or gastritis. The headaches were clearly the result of gastric auto-intoxication, and they were cured simply by stomach disinfection long before restoration of normal secretion and circulation. This case was most instructive, and has paved the way by a logical extension of its teaching to other organs and tissues—and notably through an examination of the fæces, urine, and blood

—to the solution of many another complex clinical problem.

The general sensory disturbances have also been exceedingly frequent in my experience. Paræsthesia and pruritus are the forms of sensory disturbance most commonly encountered. Formication, "pins-and-needles" sensations, with sensations of heat and cold, are, and I think in the order of enumeration, the predominant paræsthesiæ. In some cases these paræsthesiæ become of serious import. They generally occur in distinct episodes, lasting from a few days to a few weeks. Exhausting insomnia is among their effects, as the exacerbations are mostly nocturnal. One of my patients walked the streets from two to four o'clock every night for nearly a week.

Vertigo is also very troublesome in some cases. It sometimes occurs in paroxysms during the height of digestion, or when the stomach is empty. In others, it occurs whenever the patient shifts from the recumbent to the erect posture, or *vice versa*. One patient, on account of the vertigo, consumed from three to five minutes while lying down on the table in my office for colonic flushings required for a complicating colitis and severe colonic infection, and about the same length of time while rising.

Muscular weakness is exceedingly frequent as a neurasthenic symptom, independently of the weakness expressive of the general debility from inanition present in aggravated cases of gastro-intestinal disease.

And, finally, it may be stated as a general proposition that the mental state of these patients tends toward depression. Melancholia finds here a favoring condition, if not an indigenous soil.

In thus briefly pointing out the principal neurasthenic symptoms of gastro-intestinal disease I have been actuated by the belief that if the medical profession could be induced more generally to study this large class of cases in the light of comparatively recent discoveries, a real service would be rendered. The vast army of chronic invalids is growing *pari passu* with the increasing tension of modern life. In the delirious struggle of competition nervous bankruptcy is constantly happening, simply because more nerve force is expended than the dynamic powers of the organism can possibly supply. The digestive apparatus suffers like all other parts of the organism from lowered nerve function; and thus it happens that in a large contingent of the dyspeptic fraternity the gastro-enteric disease is primarily neurasthenic in character, but it rapidly becomes something vastly more than this. Is the reason far to seek? Are not secretion and motility—the principal factors in primary digestion—absolutely dependent upon nerve force? The ubiquitous and vigilant germ is ever ready to seize upon the remnants of retarded digestion, producing gases and toxins, which by chemical and mechanical irritation still further vitiate and impair secretion and motility, thus ever working in a vicious circle. The more we contemplate these questions the broader and deeper becomes their practical bearing, and the more intensely interesting, from every point of view, becomes their solution. They are foemen worthy of anybody's steel, and give an added interest and a wider beneficence to the drudgery of professional life.

107 West Main Street.

Dyspnœa.—For dyspnœa resulting from any congested condition of the lungs, try steam of ammonia with eucalyptus. Place an ounce of muriate of ammonium and two drachms of oil of eucalyptus in a quart of water, and place over an alcohol or other stove, and arrange it so that the steam will be carried to the patient.—*Toledo Medical and Surgical Reporter.*

SOME ADVANTAGEOUS POINTS IN OPERATIVE TECHNIQUE OF PELVIC SURGERY.[1]

By JENNINGS P. CRAWFORD, M.D.,

Davenport, Iowa.

In pelvic surgery we are still confronted with difficult problems, such as overcoming infection, controlling hemorrhage, lessening shock, preventing stitch abscess and subsequent hernia from imperfect union. It is my desire in this paper to present some methods which have decided advantages over others in dealing with these problems, and to describe some steps which perhaps have not been heretofore employed in connection with this division of surgery.

The first point to be discussed is controlling the hemorrhage in the removal of growths about the broad ligaments, such as hæmatomas, tubal gestations, neoplasms, and pyosalpinx with inflammatory exudates.

Before proceeding further let us notice the anatomy of the broad ligament and its vessels.

The broad ligaments are the lateral supports of the uterus. They pass from the sides of the uterus to the lateral walls of the pelvis, making a septum across the pelvis, dividing the cavity into two portions. This ligament is formed by the reflection of the anterior abdominal peritoneum downward and backward, reaching across the pelvis from side to side in front of the uterus, which constitutes the anterior layer of the broad ligament, and of the posterior abdominal peritoneum upward and backward behind the uterus, forming the posterior layer, the two joining each other at the free border of the ligaments.

In front of these ligaments or septum is the bladder; between them, centrally located, is the uterus; and behind is the rectum. The Fallopian tubes extend from the superior angles of the uterus to either side from three to four inches along the free border of the broad ligaments within its covering or peritoneum well toward the margin of the pelvis, the fimbriated or trumpet end hanging free. Also from the superior angles of the uterus the round ligaments pass obliquely outward and upward, lifting the anterior layer of the broad ligament, through the abdominal ring, and serve as anterior supports to the fundus.

The ovaries are located behind the broad ligaments near the free border, about midway to the margin of the pelvis. Each ovary is likewise covered with an investment of peritoneum, except a portion of the anterior surface which unites with the posterior wall of the broad ligament, the larger part of the organ hanging free in the abdomen.

Between the laminæ or layers of the broad ligament, which we found to be formed by the anterior and posterior abdominal peritoneum reflected backward, are located the ovarian arteries and associate veins, and the uterine arteries and accompanying veins.

The uterine arteries pass downward behind the posterior peritoneum from the anterior trunk of the internal iliac, at an acute angle with the womb and just over the ureter; coming up between the layers of the broad ligament about on a level with the cervix, and passing to the side of the uterus, they ascend in a tortuous course along this organ, distributing branches to the womb, and at about the middle of the fundus turning latterally at right angles, anastomosing with the ovarian arteries midway to the ovaries.

The spermatic or ovarian arteries arise directly from the aorta high up in the abdomen on a level with the kidneys near the renal arteries, and pass downward and obliquely outward behind the posterior peritoneum on the surface of the psoas muscle to the margin of the pelvis, where they enter the laminæ of the broad ligament. From this point they pass near the free border of the broad ligament toward the ovaries. These ova-

[1] Read before the Iowa State Medical Society, May 19, 1898.

rian arteries, as they extend near the ovaries, distribute branches forming a plexus of vessels supplying the ovaries, round ligament, and anastomose with the uterine supply, as just stated. The veins follow the course of the arteries as a rule, there being usually two veins to each artery, and are easily included in the same ligature.

It is highly important to keep in mind not only these different sources of blood supply, but to cultivate more accurate localization of vessels, so as to isolate and ligate them quickly without including half of the broad ligament, which is so often done to secure a little vessel not longer than a crow's quill and having quite constant anatomical relations.

If we wish to do expert surgery we must employ expert methods and become expert in their use; not only become familiar with the details of pelvic anatomy and its deviations, but more skilful and dexterous in the use of instruments, and raise our workmanship to the plane of art. When a hysterectomy can be made in seven or eight minutes, there is no virtue in keeping a patient on the table two hours, subject to the exhaustion and shock incident to prolonged etherization.

The increased vascularity accompanying all these growths about the broad ligament and its associate appendages is dependent upon these two sources of blood supply—the uterine by way of the superior angle of the womb outward, and the ovarian arteries from the margin of the pelvis along the free border of the broad ligament inward; and in controlling hemorrhage a knowledge of these facts is the key to the situation.

By observation the usual procedure in the removal of hæmatomas, tubal gestations, and exudates about the tube is to dig them out and stop the mouths of bleeding vessels as they are torn open.

The strategic point in the technique of these operations to my mind is the preliminary step of shutting off the blood supply before beginning the separation of the growth. This step I have not seen described for broad-ligament operations. It is accomplished by first going out near the margin of the pelvis and ligating the ovarian arteries an inch or two beyond the fimbriated extremity of the tube. A medium-sized curved needle, armed with a silk ligature, held with a strong holder, is passed through the broad ligament a good one-half inch within the free border and brought around the same and securely tied. This marginal tie cuts off the ovarian arterial supply completely before it branches within the laminæ, and the ligature is so thoroughly anchored outside of the site of the operation that it is in no danger of being dragged off by further manipulation.

The other part of this preliminary step is tying off the uterine feeders at the superior angle of the uterus. A curved needle, in like manner as before, is passed through the broad ligament about an inch below the margin, a little out from the fundus, just above the attachment of the round ligament, so as to preserve it, yet including the utero-ovarian vessels; it is then made to sweep around the cornu, and the ligature is anchored in the free border, so as to prevent its slipping. This ligature ties off the Fallopian tube and vessels, ovarian ligament, as well as utero-ovarian anastomoses within the laminæ near the fundus. The whole broad-ligament country is now high and dry, and the separation and enucleation of these juicy growths can be rapidly accomplished without hemorrhage other than slight capillary oozing.

Let me say here that I recently noticed in the removal of a tubal gestation of five months' development that, following the separation of the large placentæ, there was practically no hemorrhage, while usually the hemorrhage is frightful in such cases.

This procedure possesses special advantages in the removal of pyosalpinx or hæmatoma with thickened walls from extensive inflammatory exudate, so often found where the tissue is so soft that a hæmostat will pinch it off and a ligature cut through it or pull out with every advance step, tending greatly to prolong the operation and frequently to excessive loss of blood—both of which are elements contributing to shock and should be scrupulously guarded against.

In cases in which it is necessary to make a hysterectomy in connection with these broad-ligament exudates, instead of ligation at the superior angle of the womb, the uterine arteries are tied off separately at the side of the neck a little below the union with the fundus and the round ligament, in its course upward. This permits the removal of the fundus at its union with the neck, along with the diseased appendages, with the same freedom from hemorrhage.

This operation is entirely different from the method in common use in hysterectomy, in which the ovary is lifted up and a ligature passed into the broad ligament, including the ovarian artery and round ligament midway to the pelvic wall. In this operation the ovarian artery is ligated out at the margin of the pelvis before any branches are given off. The method is especially applicable in operations with extensive growths about the broad ligament, either with or without hysterectomy.

The next point is the closure of the abdominal wound. Notwithstanding the great variety of suture materials and the many different methods of stitching, the dangers of stitch abscess from infection, resulting in imperfect union and subsequent hernia, have by no means been entirely eliminated. The most common practice for the last few years has been the buried continuous suturing of the three layers separately. Of buried silk it may be said that when the wound heals kindly, as it usually does, it serves admirably; but in the presence of suppuration it is annoying, to say the least.

Catgut, on account of being so quickly absorbed, does not possess the elements of strength when put to the test by delayed union from stitch abscess, aggravated vomiting, or coughing, which most other suture materials do.

To my mind the correct principle in closing the abdominal wound is by the use of a suture that has great strength, that approximates the surfaces, and relieves the tension from the healing margin, and one that can be entirely removed at will.

The silkworm gut, used as a deep interrupted through-and-through suture of all the layers of the abdominal wall about three-fourths of an inch apart, is undoubtedly the best calculated to meet these requirements. This form of suture is at present in high favor with many of the advanced gynæcologists.

Some one is already saying, no doubt, that this is an old stitch that has been used for years, but I think that a moment's explanation will disabuse any one of that wrong impression. The old stitch passes through all the layers at an equal distance from the margin of the wound, without providing for the coaptation of the fascial layers, which must be relied upon for the strength of the union; consequently, the tension being on the fascial layer, its margins are separated and a gap is the result. The deep interrupted stitch is used now; the needle is passed through the skin and fatty layer a half-inch from the margin, and while an assistant pulls the fascial layer with a hæmostat in toward the centre, the needle is passed on through this layer fully one and one-fourth inches from its margin, continuing through the peritoneum at one-half inch from the margin, the same as the skin layer, and then coming up through the opposite side in like manner. When this ligature is tightened in lifting up the abdominal walls the peritoneal layer is brought together; also skin and the middle layers cannot help being in forced

apposition on account of the superabundance of tissue provided for in drawing the fasciæ out while inserting the sutures.

This stitch, while it so thoroughly provides for the apposition of the middle layers, does not assure to a certainty coaptation of corresponding tissue, as the fascial layer may slide past its opposite fellow and project against adipose instead of fascia. To overcome this tendency, I have made a modification of this stitch in my work by introducing a silkworm-gut, longitudinal, running stitch in the margins of the fascial layers before the interrupted abdominal stitches are tied and while the wound is still gaping. This stitch is taken like a basting-stitch, in and out, across from one margin to the other. It is tightened as the interrupted sutures bring the walls together by drawing on both ends as they are left protruding through the integument at each angle of the wound, something like the subcuticular stitch, only in the fasciæ. This nicely adjusts the margins of the fasciæ in perfect approximation. No tension whatever is put upon this coaptation stitch after the row of interrupted sutures is tied. It is best, however, for the ends to be shotted where they emerge through the integument, so that they may not retract, especially in a thick, fatty abdomen. This buried suture is to be removed when the others are, and this can be easily done by drawing it forward in the same direction it was inserted, providing the needle was directed constantly forward and no back stitch taken, in which event it will lock and have to remain, the same as any other buried suture, though with a little care in its introduction it is not necessary for this to occur.

To sum up the merits of this suture, it can be said that, being deep and wide, it masses together a large amount of tissue and secures the heaviest possible scar line; that, on account of the stitches being set far in from the edge, it removes all tension from the margins of the wound; that, as modified, it adjusts the fascial borders to perfect coaptation; that it can be removed when its purpose is served; and finally, being of silkworm gut, it is the least likely of all material to introduce infection, and in case of stitch abscess, being interrupted, one stitch can be removed to secure drainage without destroying the whole suture line.

But neither with this suture nor any other can we eliminate all danger of stitch abscess, for it has been proved that cultures may be made from almost all these wounds from hand infection, although usually not to the extent of causing stitch abscess or impaired union. In over one hundred abdominal sections made in our Davenport hospitals by our surgical staff in the last year, under the most careful supervision, we have had, taking pus cases and others just as they come, stitch abscess in at least ten per cent. of our cases—an experience not different from that of others.

While the name stitch abscess stamps a curse upon the suture, the fact is that the layer of fat, from one-half to two inches deep, with its low vitality, subjected to the dangers of hand infection by an hour or two of constant abuse and handling, which still further lowers its resistance to bacterial attack, is largely responsible for this unfortunate and apparently unavoidable condition in a percentage of cases. Possibly there may be something in the explanation that the air follicles are deep down in the true skin, with the sebaceous glands pouring out secretion alongside through the tissues to the surface, and also deep in the same stratum the coiled loops of the sweat glands, and that all these tubules contain bacteria. It is certainly impossible, with any of our methods of applying antiseptics, to reach germs hidden in the meshes of these buried passages. In placing a suture we pass through this network of excretory ducts with their excrementitious matter. I know of no suture material that as a foreign body is calculated to excite less noxious influence under these conditions or contribute less to bacterial activity than silkworm gut.

This suture material is open to the same danger, however, as any other in being tied too tightly, causing death of tissue by mechanical pressure, which furnishes favorable culture ground for the pus germ—no doubt a very common factor in the production of stitch abscess.

Progress of Medical Science.

Icterus of the Newborn. — Two main classes of icterus are described by Drs. Lesage and Demelin (*Revue de Médecine*, January, 1898): 1, that derived from changes of the blood (hæmatogenous icterus); 2, infectious icterus, due to germs finding their way into the bile passages. The first group (hæmatogenous icterus) begins spontaneously in the first days of life, is not malignant, and is to be diagnosed when no bile pigment is found in the blood. The yellow color of the skin is not caused, as in the second class, by a particularly marked cutaneous congestion; both writers are of the opinion that the coloration is probably due to the red-brown pigment isolated by Winter. This latter pigment is derived from the hæmoglobin, which is set free in large quantities, the liver cells not being sufficiently active to change this hæmoglobin into bile pigment. This simple icterus—which, according to the authors, is a proof that the system is trying to get rid of its plethora—is really not a disease, is physiological, and needs no therapy. Infectious icterus is either of intestinal derivation, in that the infectious agent (generally bacillus communis coli) finds its way from the intestinal canal to the bile passages and liver; or is of puerperal nature, in that the germs find their way directly into the liver from the stump of the umbilical cord. In the former there is an especial form of diarrhœa (pale green, alkaline), with mild fever; the disease may occur isolated and in epidemics. In the latter form (*i.e.*, from an infected stump) the severer cases are complicated by hæmaturia and sometimes by hemorrhages from the other internal organs. Puerperal icterus is rare at present; it formerly occurred in connection with septic infection of the stump, with symptoms of septicæmia, high fever (39°–40° C.). Another form of icterus is that due to malformation of the bile passages. A few hours after birth icterus of a very intense form occurs, the fæces are colorless and have a fetid odor, the abdomen is distended, the pulse rapid. The child becomes somnolent, and dies during the first week.

Tuberculosis of the Pharynx in Children. — Dr. Plicque (*Annales des Maladies de l'Oreille*, etc., No. 3, 1898) says that this disease is much rarer in children than in adults. The disease may be secondary (infection from the respiratory apparatus) or primary; its favorite sites are the uvula and tonsils, occasionally the epiglottis and the nasopharynx. It is to be diagnosticated from diphtheria and lupus. Pharyngeal tuberculosis often shows diphtheritic-like pseudo-membranes, which disappear rapidly when pencilled with lactic acid. The absence of Loeffler's bacillus, the eventual discovery of the tubercle bacillus; little or no fever; gray, translucent, millet-seed nodules, sometimes seen in cheesy degeneration: long duration, etc., would exclude diphtheria. In lupus the nodules are larger, the cervical adenitis is less, scars are found, and very often other portions are affected by lupus (face, nose). Dysphagia is sometimes so marked and painful that the patient must receive his nourishment by artificial means. All the cases thus far reported have ended fatally, very often after a comparatively short illness.

X-Rays in Military Surgery.—Professor Küttner, of Tübingen, who followed the last Greek war in connection with the German Red Cross Society, has made some interesting experiments with the Roentgen rays at the Constantinople Hospital. In his report just issued he says, that while the apparatus proved of service when applied with the screen it was rarely possible to take a satisfactory photograph, on account of the difficulty of bringing the patients into the proper position. The former method proved often the only way to ascertain the site of a projectile which had entered the body and remained there. This was applicable to all parts of the body except the stomach and head. A bullet in the brain, for instance, showed very indistinctly. (Last spring an arrangement of mirrors exhibited at a *soirée* of the Royal Institution, where a photograph of the brain showed in relief, enabled the operator not only to see the foreign body, but also to measure correctly the distance from the outer wall of the cranium). Professor Küttner says it is noteworthy that splinters of bullets and of bone which had penetrated into the soft parts of the body could not be distinguished from each other. Also, he says, it was proved that the opinion that deep-lying masses of pus could be located was erroneous. Injuries to the central nervous system, the spinal cord, and the peripheral nerves were solely ascertained by the aid of the Roentgen rays. It was impossible to do this before. Furthermore, it could be seen whether a bone was wholly or only partially severed—a matter of great importance as far as therapeutics is concerned. For shot wounds in the extremities he recommends that a photograph be taken. His conclusion is that the Roentgen rays are of great importance for medical aid in war, but only for fixed hospitals, such as reserve hospitals and those installed in fortresses, while for moving field hospitals their application is very limited.—*The Lancet.*

Arsenic as an Antidote to Thyroid Extract.—MM. Bedard and Mabille, of Lille (*Gazette Hebdomadaire*, May 29), have proved by experiments on dogs that arsenic is an antidote for the thyroid extract. It is known that authors say that large doses of the extract from the thyroid gland have caused serious disturbance in the action of the heart. These evidences of heart poisoning are easily obtained by feeding dogs on the thyroid gland. If, while the animals are using the thyroid, they are given arsenic at the same time, in the form of Fowler's solution, the glandular substance may be given freely without producing any cardiac disturbance. It seems, therefore, very desirable to give arsenic when treating patients with extract of the tyroid gland.—*The Lancet.*

The Treatment of Lupus by Injections of Calomel.—On July 7th, M. du Castel showed at a meeting of the Society of Dermatology two patients suffering from tuberculous lupus of the face, who had been treated during the past six months by injections of calomel after the method of Asselbergs. The good results of this treatment were very marked. M. Gaucher considered that, as a rule, cases of lupus cured by mercurial injections were errors of diagnosis. M. Brocq had seen in one case the mass of lupoid infiltration diminish under this treatment, but he did not know whether the result was permanent. In another case he had seen some amelioration, but afterward the lesions remained in stationary condition, and it became necessary to attack them with the cautery. He thought, too, that the patient was syphilitic. M. Fournier was of the opinion that an occasional case of wrong diagnosis might occur, but he considered that there was possible association between lupus and syphilis. Antisyphilitic treatment certainly brings about a considerable, if fleeting, improvement in cases of lingual epithelioma. Lupus in a syphilitic patient is probably seriously increased by the soil on which it grows, and this is probably the key to the results obtained by Asselbergs.—*The Lancet.*

Lactation Atrophy of the Uterus.—1. Modern researches tend to prove that postpuerperal involution consists chiefly in a retraction and contraction of the individual muscle fibres, whereby the whole uterus is reduced in size. 2. When involution goes to its full completion the uterus is reduced to a size smaller than that of the nonparous organ. 3. This condition of complete involution is known as postpuerperal hyperinvolution. It is principally seen in nursing women, and from this circumstance has received the cognomen lactation atrophy. 4. The so-called lactation atrophy is a normal and desirable condition. It is temporary in its duration, but very rarely under favorable circumstances may become permanent. 5. When the parturient is unable to perform the function of lactation it is the duty of the physician to endeavor to bring about hyperinvolution by other means at his disposal. An observance of this course will prevent many a woman from developing a host of gynæcologic affections which frequently result from imperfect involution.—VINEBERG, *American Journal of the Medical Sciences.*

Indications and Operative Treatment of Retrodeviations of the Uterus.—S. Pozzi divides retrodeviations into two general classes: the free and the adherent. Free retrodeviations he again subdivides into two headings: 1. Free, movable retrodeviations. They are relatively rare, and are caused by laxity of the ligaments; this retrodeviation is not constant, but is the generally occupied position of the uterus. 2. Free retrodeviations which can be made movable. This condition is found most frequently in multiparæ; the anatomical examination shows a large corpus uteri with a flexible cervix. In both of these classes of retrodeviation, the extraordinary movability of the uterus, and not its malposition, is of main importance. The uterus must be made more stable, which condition can be fulfilled only by putting the uterus in normal position. When the uterus is thus replaced, it must be fixed there, but not by means of vagino-fixation or ventro-fixation. If a metritis exists, curettage should be done; if the perineum is weak, an operation to strengthen it should be performed. As means of fixing the uterus *per se*, pessaries and abdominal binders are of importance and value. Pozzi places in a separate division the movable retrodeviations with diseases of the adnexa. Laparotomy, with eventual ignipuncture or resection of the ovaries, is here to be thought of. If both ovaries have been removed *in toto*, fixation of the uterus is not then necessary. If the adnexa of but one side have been removed, the stump can be sewed in the lower angle of the wound. If only ignipuncture or resection of the ovaries has been resorted to, then a ventro-fixation may be done, though it is by no means absolutely necessary. Fixed retrodeviations: In order to diagnose between this condition and movable retrodeviations, bimanual reduction in the knee-elbow position must be tried; if this does not succeed, the same attempt must be made under narcosis. The vagina is held open by a speculum. If the uterus is diseased, appropriate treatment must be instituted. If the adnexa are diseased, laparotomy and conservative treatment are necessary. Laparotomy is performed, not to tear the adhesions, but because of the diseased adnexa. When the uterus and adnexa are freed, the ovaries and tubes are to be examined; it is generally impossible in these cases to treat all adnexa conservatively. If at the same time the uterus is very much diseased, it should be removed with the tubes and ovaries.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 10, 1898.

TROPICAL DISEASES.

A CELEBRATED medical man some time ago uttered the wail in Calcutta that although French, Germans, Russians, and Poles—to the list he might have added Italians—had done much in the investigations of the malarial parasite, Englishmen had done nothing. At the time when the remark was made, the complaint was perfectly true. Laveran gave us the germ. Roque and Lemoine proved the increased toxicity of the urine after the "accès" in intermittent fever. Roux and Chamberland suggested that after the "accès" the toxins secreted by Laveran's parasite conferred immunity for a certain period. Mosse was the first to notice the appearance of polyuric "aiguë non diabétique" so frequent after attacks of intermittent fever. In fact, the whole subject of malaria may be said to have belonged up to quite recent times to France.

The study of tropical diseases in this country and in Great Britain has been a neglected department of medical education. There are two sufficient reasons for this neglect in Great Britain, according to Dr. Patrick Manson, one of which is that men going in for a medical examination never think of spending any of their time over the study of diseases incidental to a hot climate, as they are well aware that they will not be asked questions bearing on the subject; and the reason that the examiners do not ask these questions is because they have not practised in tropical countries, and have had no practical knowledge of the diseases peculiar to them. In the tropics malaria is undoubtedly the most deadly disease met with, and yet the ignorance of the newly qualified medical man concerning it is stupendous. He knows nothing about the malaria germ and would not be able to recognize it if he saw it. Dr. Manson aptly sums up the situation in these words: "What would an examiner nowadays do with a student who could not recognize and demonstrate the tubercle bacillus? He would pluck him; and if I were an examiner and found that a student, intending to practise by-and-by in the tropics, could not recognize and demonstrate the malaria parasite, I would do the same." Of late years, however, both in America and in the British empire, the claims of tropical medicine have become more pressing in consequence of the investigations and discoveries made in tropical pathology. The successful result of Sanarelli's researches as to the origin of yellow fever; the investigations of Kitasato, Haffkine, and others with regard to the cause of the bubonic plague; the light recently thrown upon the secrets of malaria by many scientific workers, have given the much-needed fillip to a study of the diseases of hot climates; and the day seems to be not far distant when the systematic teaching of tropical medicine will be universal in the medical schools of America and Great Britain.

At the Edinburgh meeting of the British Medical Association a new departure was made; for the first time since that association was founded a section was set apart for the consideration and discussion of tropical diseases, and it is gratifying to have to record that the experiment proved a most unqualified success. The proceedings in this section evoked the greatest amount of interest, and it was the most largely attended of any of the sections. Many able papers were contributed, but decidedly the most important was that read by Dr. Manson, describing the researches of Surgeon-Major Ronald Ross, on the extra-corporeal life of the plasmodium malariæ and the result of his investigations with regard to the connection between the mosquito and malaria. The climax was reached when Dr. Manson announced to his auditors that he had just received a cablegram from Dr. Ross, reporting his discovery that a parasite-bearing mosquito is able to infect a healthy bird. There can be no doubt that this discovery is of the utmost value, and will probably in the near future lead to further developments. *The Lancet*, referring to the matter, says: "Thus the analogy between bird and human infection has only to be proved to establish that the mosquito is a carrier of malaria and an infecter of man. Much has yet to be done, however, before the full significance of the mosquito and malaria is worked out. Malaria, we know, multiplies without the intermediary of any vertebrata. Does it do so solely in mosquitoes? If so, we have yet to learn how it passes from mosquito to mosquito. Does it multiply in other media? If so, what are they? . . . The practical applications of the discovery are immeasurable, and the establishment of the fact, that as the bite of the snake or of the rabid dog inoculates the blood of the victims of these creatures, so the mosquito conveys malaria, would open up a new and hopeful phase as regards the prevention of disease in the tropics."

With regard to the influence of plague inoculation on other diseases, Haffkine endeavors to show not only the protective value of inoculation against the plague, but that it influences also favorably the resistance to certain other diseases. Whether this be so or not has yet to be proved, but at all events it is certain that plague appears to have an antagonism to malaria; and it is very suggestive that inoculation for plague should exert a favorable influence on the subject of malarial disease. Investigations are now being made into every branch of tropical diseases, and an increasing sense of their importance is obtaining daily. With the impetus thus given to their consideration, the outlook for the solution of the difficulties surrounding their origin and treatment should be hopeful.

DISPARAGEMENT OF THE REGULAR ARMY SURGEONS.

Among all the accusations of executive incompetency brought by the press of the country against the medical department of the army, we have seen but two attacks made upon the professional attainments of the members of the medical staff. These attacks appeared simultaneously: the first anonymously in a non-medical paper in this city; the second, over the signature of Dr. N. Senn, of Chicago, in the *Journal of the American Medical Association* of September 3d. In an article on "The Qualifications and Duties of the Military Surgeon," Dr. Senn says, basing his conclusions on an experience of five months in the camp and field, that the surgeons of the United States regular army, while men of superior education and splendid physical development and (those who have been in the service several years) well versed in the routine work of the medical department, are inferior in all matters pertaining to medicine and surgery to the national-guard surgeons.

The slur cast upon the army medical corps by the writer in *The Criterion* did not surprise us, for the people of the country, especially those in New York, who have seen shocking sights with their own eyes, are so fierce in their wrath that they must find some one upon whom to vent it. The complacent assurances of the executive in each department of the army, staff and line, that everything has been done for the soldier that could be done, coupled with the trite remark that war is not the equivalent of a summer vacation, would naturally, if believed in, leave one no alternative but to conclude that the unnecessary sufferings of the sick and wounded were due to incompetence of the doctors. We little expected, however, to see the same charge made in a medical journal, over the signature of one whose reputation as a surgeon and whose position as the predecessor of the surgeon-general of the army in the presidency of the American Medical Association will give his words, in the minds of many of his readers, all the weight of indisputable authority.

The inferiority of the army surgeon, Dr. Senn says, is the natural outcome of circumstances. "The young army surgeon has to spend many years at small and often out-of-the-way posts, where the opportunities for clinical experience and intercourse with professional colleagues are necessarily limited. He naturally soon falls into the monotonous and routine work of the post life, with little or no inducements to continue his post-graduate scientific and medical studies. When the time comes to pass an examination he wakes up from his lethargy sufficiently to go through the different compends to prepare himself for the coming ordeal. He breathes easy after he has reached the major's rank, as this promotion forever closes the door of the much-dreaded green room. From now on he is in the line of slow promotion without any extra exertions on his part. He receives his salary and looks confidently for assignments to posts where he can spend the balance of his life in ease and luxury. He has reached a time in life when he feels that he can avail himself of the work of his subordinates without interfering with his emoluments or his position in social and military life. He is conscious of the fact that he has reached a rank and a station in life where it is proper for him to look to his assistants to do the drudgery which he had become accustomed to in the past, and begin to enjoy the life before him." Then follows a list of the reasons why the military surgeon taken from civil life must be far better than his colleague in the regular army.

Leaving aside the question of taste involved in such a comparison made by one who is himself a "military surgeon taken from civil life," we cannot regard this public disparagement of the army medical corps as other than cruelly unjust. The surgeon-general of the army is known the world over as a man of far more than ordinary professional attainments and as a bacteriologist of the first rank. The worst that has ever been said of him is that his executive ability is not on a par with his scientific acquirements. The deputy surgeon-general is another who has reached the major's rank and so "breathes easy" and "receives his salary." He may not be able to perform a laparotomy as rapidly and deftly as some military surgeon taken from civil life, but we never before thought of him as the inferior of the "average national-guard surgeon." But Dr. Senn implies that he bases his opinion of the army surgeon upon his experience in the present war; so perhaps he does not intend that his strictures should apply to the higher officers serving in Washington, but rather to those who were his comrades in camp and on the field, and of whose inferiority he can speak from personal observation. Among these, to mention only a few who have attained the major's rank and "breathe easy," we find Major Havard, Major La Garde, and Major Wood at Santiago; Major Torney and Major Bradley on the *Relief;* Colonel Greenleaf, Colonel Hartsuff, and Major Maus in Porto Rico; and Colonel Forwood and Major Brown at Camp Wikoff. There were others in the regular army, at Chickamauga and elsewhere, associated with Dr. Senn during his five months of service, but the names above mentioned are sufficient to show the utter baselessness of this attack upon the professional standing of the army surgeon. The question is absurd and not worth an argument. Any one who has ever come in contact personally or professionally with the members of the medical corps of the United States army knows that, possibly with rare exceptions, they are the equals in scientific attainments of their professional brethren anywhere in the country.

Drowned in Dust.—A coroner's jury in an Iowa town recently returned a verdict that a man found dead was "smothered to death in the dust of the public highway." The man was a ranchman who left the town for his home, some miles distant, in the hottest part of the day. A mile from town he was overcome by the heat, and possibly by his potations, and fell from his horse. The dust at this place was several inches deep and very fine. The man fell on his face and was unable to turn over.

REST IN THE TREATMENT OF SKIN DISEASES.

The address delivered by Dr. Allan Jamieson at the Edinburgh meeting of the British Medical Association dealt with the above subject to a somewhat limited extent. The author expressed himself in a manner suggestive rather than didactic. After alluding to the fact that rest as a means of treatment of skin disease has received but little attention in works on dermatology, Dr. Jamieson gives the following definition of rest in a medical and surgical sense: "What is meant by rest? Certainly not absolute inactivity. This the surgeon may aim at, at all events for a brief preliminary period in the coaptation of fractured bones; but even he has very early to think of the tendons, muscles, vessels, and nerves in the neighborhood, to say nothing of the related joints, which would all suffer were complete quiescence insisted on for too long a time. Absolute rest is impossible in the case of the skin. . . . But while it may be out of our power to procure by the means at our disposal absolute and entire quiescence, comparative compose is attainable, and this in the great majority of cases is sufficient for our purpose. Rest then consists in the removal of irritants, whether these be such as worry and distress the mind or tense and vex the body." The need of rest for the skin is then especially dwelt upon, and it is pointed out that the term eruption itself implies disturbance and calls for rest.

With regard to eczema Dr. Jamieson says: "Whatever view of the nature of eczema may be determined on in the discussion which is to follow, its relation to catarrhal processes cannot be overlooked, and our most successful efforts to cope with it are those which follow the lead given by this theory. It does not matter whether we regard it as a parasitic catarrh or not, provided we bear in mind that it is a catarrh. We treat it on the same principles as we do an internal catarrh, though we can apply remedies which are impracticable in the case of internal catarrh. Just as in bronchitis we endeavor to soothe the inflamed and irritated mucous membrane by keeping the air of the apartment continuously moist and warm, so in eczema we envelop the raw, denuded, oozing surface with a soft, bland, aseptic medium. A starch jelly, with which is combined a proportion of boric acid, is the least irritating if perhaps the weakest of our available correctors of putrefaction."

After drawing attention to the extreme sensibility to light observed in some skin diseases, as xeroderma pigmentosum, and the successful results obtained by treating such cases with brown ointment, and by covering the face when out in the air with a dark brown veil, thus procuring perfect rest for the abnormally tender skin, Dr. Jamieson proceeds to a consideration of the means to be pursued to secure rest in those skin diseases caused by parasitic agencies, and in the case of erysipelas concludes that the treatment of erysipelas by strong ichthyol ointments affords one of the best examples of medicinal rest to an inflamed skin that can be cited.

An able and instructive paper is brought to a conclusion by pointing out that rest is an important factor in the cure of syphilitic affections of the integument.

THE END OF COMPULSORY VACCINATION IN ENGLAND.

By far the most important event which has occurred in the English medical world within the memory of the present generation has recently been consummated. The compulsory vaccination bill has been practically rendered of no effect in England. For many years there has been a persistent and strenuous opposition on the part of a small but irreconcilable minority against the vaccination laws, and now we see the strongest government of the century giving way to the importunate demands of a small but particularly assertive class of the community, although by its own showing strongly convinced of the efficacy of vaccination. In this country the antivaccination sentiment in England seems quite incomprehensible, so strong is the belief here that vaccination is a preventative of small-pox. On the European continent the faith in the comparative immunity conferred by vaccination is universal. Since 1875 Germany has vaccinated every infant and revaccinated every child before it has reached the age of thirteen years. The success of that experiment is testified to by Gerhardt, who wrote in 1896 that the disease had almost died out in Prussia. In the face of all these convincing proofs, England, the home of Jenner, is the first country to throw doubts on the value of vaccination. The measure agreed upon provides that no parent will be convicted for refusing to vaccinate a child if he satisfies the court that he has conscientious scruples as to the beneficial effects thereof. There can be no doubt, judging from the prejudices among the lower classes against vaccination, that these scruples will multiply exceedingly, and that soon the law will to a great extent have become a dead letter. The strong stand taken in England against vaccination is due principally to two causes, one of which is the increasing ignorance of the ravages of small-pox, and of the terrible mark which those who escaped with life had to bear until Jenner's treatment came into use, and the other reason is the difficulty of procuring good lymph, and the carelessness of many medical men in performing the operation. So far, now, however, as the lymph supply is concerned, the reproach of evil consequences from that cause is removed, the public provision of glycerinated lymph insuring a pure article. One feature of the case worthy of notice in connection with the antivaccination crusade in England is the fact that almost without exception the lay journals side with the medical journals in opposing the bill just passed. *The Times* says that the strict enforcement of the law of compulsion, even though it only authorized the infliction of a single penalty, would have gradually brought home to the minds of the parents the fact that vaccination could not be omitted without inconvenience and pecuniary loss, and the fact that when performed it was no longer followed by the evil consequences which, in a very

small proportion of cases, had been at least supposed to arise from it. In the words of Lord Lister, England is going to undertake a tremendous experiment, and we may add that it is one that will be watched with intense interest by all countries of the civilized world.

News of the Week.

A Week of Intense Heat.—It is seldom that New York is subjected so late in the season to such a prolonged period of high temperature and humidity as that through which we have just passed. The hot wave appeared on the 1st of September, on which day there were 2 deaths from insolation. The effects of the heat became apparent the following day, when there were 28 deaths caused directly by the high temperature. On the 3d of September the deaths numbered 61; the 4th there were 56; the 5th, 47; the 6th, 12; and the 7th—the last of the excessive heat—the mortality was 10. The total number of deaths from heat stroke during the week was therefore 216, and the number of cases of non-fatal heat prostration reported to the police was over 600. The mortality of the week indirectly caused by the heat was especially heavy among babies. A report issued by the board of health gives the number of deaths of children under two years for the first five days of the week as 240. Of this number 139 were male children and 101 female.

Small-Pox at Put-in-Bay.—There has been an outbreak of small-pox in a hotel on Put-in-Bay Island in Lake Erie. A week ago there were twenty-seven cases on the island. One death had occurred and one patient escaped to the mainland. The others are confined in a pest house near the hotel, which is well guarded to prevent any more from running away.

The Sanitary Condition of Camp Wikoff.—If the sanitary conditions are not as they should be at Montauk Point, the fault does not lie in the want of inspection. First the secretary of war visited the camp and pronounced it good; then the President went there and was apparently not quite so pleasantly impressed; finally the surgeon-general made a personal inspection of the hospitals and said that he found them in excellent condition. There was plenty of everything needful—doctors, nurses, and medicines—and the sanitary condition of the hospital could hardly be improved. Concerning Montauk Point as a site for an army camp, Dr. Sternberg is reported as saying that he could only reaffirm what he said in his original report about the place when he first inspected it. A better site could not be found on the Atlantic coast. Not only is it healthful, with good air and comparatively pure water, but it is so isolated that there is absolutely no danger of infection to the centres of population. He disagreed entirely with Dr. Senn as to the danger of contamination of the water supply and the consequent spread of typhoid fever. The water is filtered through two layers of clay and sand about one hundred feet deep, and when drawn to the surface is practically pure. The disease which gave the most trouble, Dr. Sternberg said, was malaria, and while there were some cases of typhoid fever at the camp, the number was not very large. It is possible that the actual number of typhoid-fever patients in the hospital is not large, but the facts related by Dr. Thompson in another column would indicate that the infection is widespread, and that the reason more cases are not in the hospital is that many are transported to New York before the disease has declared itself or has been discovered by the surgeons.

Yellow Fever.—There have been reports during the past week of cases of yellow fever at several places in Mississippi and Louisiana, especially at Orwood and Taylor in the former State. Two "suspicious" cases were reported at New Orleans by the Louisiana State board of health, but upon careful investigation they were declared not to be of yellow fever. Quarantine against places where genuine cases of the disease are known to exist has been declared by Memphis, Jackson, Mobile, and other towns. Officers of the State boards of health and of the Marine Hospital service are sent to investigate all new cases reported, and the authorities are very hopeful of being able to confine the fever to the infected districts, which are ordinarily healthy and are not densely populated.

The War Tax on Drugs.—Several manufacturers and drug importers of New York are trying to convince the commissioner of internal revenue that his classification of the various coal-tar products as medicinal chemical compound preparations is erroneous. They contend that these substances are uncompounded, and as such not subject to tax. The commissioner will not reverse his decision, but has directed a revenue agent to seize some drugs of this kind found unstamped, in order that a test case may be brought before the courts for a judicial decision.

The Prevention of Tuberculosis.—The Congress for the Study of Tuberculosis, recently held in Paris, declared officially that contagion is the most important cause of human tuberculosis, and that sputa dried and reduced to dust are the most effective agents of contagion. Acting upon this theory of the spread of the disease, the congress recommended: 1. That until the time arrives when tuberculosis will be included among the contagious diseases the notification of which is compulsory, all places open to the public should be provided with hygienic spittoons, and with a conspicuous notice forbidding expectoration anywhere else than into these receptacles. 2. That the public authorities order the execution of this measure with the least possible delay in all places under their jurisdiction, and especially in schools of every class. 3. That tuberculous patients should not be sent to convalescent homes open to persons suffering from other diseases. 4. That homes should be established and specially reserved for convalescent children. 5. That a medical committee should be formed for the establishment of sanatoria where the poor may be treated without charge. 6. That these sanatoria should be as numerous as possible. 7. That the authorities encourage by an official patronage courses of instruction in hygiene similar to those which the league against tuberculosis is now organizing in Paris

in each *arrondissement*, with the idea of extending this movement to the other towns of France. 8. That the permanent committee of the congress make an official application to the general management of the universal exhibition of 1900 to bespeak its interest in the work of prevention of tuberculosis, by studying, in conjunction with the committee, the form in which instruction should be given to visitors to the exhibition as to the means whereby tuberculosis is contracted and can be avoided. 9. That periodical international meetings be held for the study of tuberculosis, especially its prophylaxis. 10. That governments should endeavor to devise means of preventing or repressing the fraudulent use of tuberculin for the purpose of concealing the existence of tuberculosis in animals intended for sale or exportation. The congress, further considering that the constant increase of bovine tuberculosis gravely threatens public health, and that contagion is the sole truly efficient cause of this increase, insisted upon the urgent necessity of legislative measures looking to the separation of diseased from healthy animals, the prohibition of the sale of diseased animals, the supervision of cowhouses devoted to the production of milk intended for public use as food, and the immediate slaughter of every cow affected with tuberculous mammitis, the sterilization or pasteurization of milk intended for the production of butter and cheese on a large scale, and the generalization of the service of inspection of butchers' meat.

Missouri State Medical Association.—At the annual meeting of this association, held at Kansas City in May, the following officers were elected: *President*, Dr. George Highsmith, of Carrolton; *First Vice-President*, Dr. W. A. McCandless, of St. Louis; *Second Vice-President*, Dr. C. F. Wainwright, of Kansas City; *Third Vice-President*, Dr. W. S. Allee, of Olean; *Fourth Vice-President*, Dr. J. D. Brumell, of Salsbury; *Fifth Vice-President*, Dr. W. B. Lucas, of Mendon; *Secretary*, Dr. A. F. Dresel, of Sedalia; *Assistant Secretary*, Dr. B. C. Hyde, of Kansas City; *Treasurer*, Dr. U. S. Wright, Fayette. The next meeting will be held in Joplin.

The Plague in Bombay.—The epidemic has entered upon another period of recrudescence in Bombay, after a remission during June and July similar to that of the year before. Last year the mortality was slight for a period of twenty-two weeks, but this year for one of eight only. The number of deaths has been steadily increasing from thirty-eight in the week ending July 5th to two hundred and thirty in the week ending August 27th.

Obituary Notes.—Dr. William Henry Bennett, of Brooklyn, died at his home in that city, on September 1st, aged fifty-four years. He was born in Brooklyn, where he received his early education, and was a graduate of the University Medical College in the class of 1870. He was a member of the Kings County Medical Society. He is survived by a widow and three sons.—Dr. W. S. McNairy died in Washington on September 3d, at the age of eighty-one years. He was born in Tennessee and was graduated in medicine from the University of Pennsylvania. In 1852 he entered the government service as a clerk in the navy department, and served at his desk almost continuously up to five days before his death.—Dr. J. K. Hogan, of this city, died on September 3d. He was born in Ireland, and was a graduate in medicine of the Long Island College Hospital in 1888.—Dr. John L. Neilson, medical inspector at the Charlestown navy yard, died suddenly in Boston on September 1st. He was in his fifty-fourth year, and had been twenty-nine years in the service. He was a graduate of the Medical College of Ohio in 1866. A widow, a daughter, and a son, who is also a naval surgeon, survive him.—Dr. Thomas S. Robertson, of this city, died September 7th, of pulmonary trouble and exhaustion resulting from the excessive heat. He was born in Glasgow in 1854, and began his medical studies in London, being a pupil of McNamara. In 1875 he came to this country and took a degree of M.D. in 1879 after a course of study at the University of Vermont. He was a member of several medical societies and other scientific and social organizations.

A Surgeon in Disgrace.—A surgeon in one of the volunteer regiments was tried recently by court-martial on the charge of desecrating the graves of Confederate soldiers at Bull Run, near Manassas. He was acquitted of the charge of having participated in the desecration, but was found guilty of having failed to exercise his authority as an officer in not stopping the desecration, and putting the men so engaged under arrest. The finding of the court-martial was that the surgeon be deprived of his rank for two months, be confined to regimental camp, and forfeit half his pay for the same length of time, and that he be reprimanded by the commanding general. In the mean time, however, he was arrested by the sheriff of the county in which the desecration of the graves occurred, and was held to answer an indictment charging him with the offence of which the court-martial acquitted him.

Cottage Hospitals.—Many of the summer residents of the eastern end of Long Island are turning their cottages into temporary hospitals for the treatment of sick soldiers from Camp Wikoff. Ten are being cared for in this way at Bay Shore and twelve at Islip.

A Meat Diet Necessary in England.—An English provincial journal states that the members of the Dominican Order in that country have received permission from Rome to eat flesh four days a week instead of perpetually abstaining, as heretofore. In cases of ill-health or specially hard work meat is to be allowed at the principal meal on every day except Friday. This decision has been arrived at after a very careful medical and official scrutiny as to the effects of perpetual abstinence from meat in a variable climate like that of England. The result is that vegetarianism has been declared incompatible with good work. If Haig's theories are correct, we shall soon see the gentle friars and nuns hobbling about with inflamed joints, racked with headache, and souring as to their disposition as only the temper of a "uricacidæmic" sufferer can be soured.

The Passing of the Retail Pharmacist.—At the annual meeting of the American Pharmaceutical Association, held recently in Baltimore, Mr. Joseph Feil, of Cleveland, read a paper showing that the number of drug stores in the country is progressively decreasing, not only relatively to the population, but actually. The decrease varies in different parts of the country, ranging from 1.8 per cent. in Pennsylvania in the last two years to 24.6 per cent. in Texas. The total number of drug stores in the United States in the years 1896, 1897, and 1898, was said by the reader of the paper to be respectively 37,664, 36,463, and 35,467. Within the same period the number of wholesale druggists also decreased from 296 to 284. The reasons for the decrease, Mr. Feil believed, are the competition of the department stores, particularly in toilet articles, and the wide practice of price cutting on proprietary medicines, to which might be added the growing custom among physicians of giving remedies in tablet form instead of writing prescriptions. Mr. Feil said that when the retailers number about 25,000, and the wholesalers about 200, equilibrium will be established and the decrease in the number of pharmacies will cease.

Examination for the Army Medical Service.—An army medical board will be in session at Washington City, D. C., during October next for the examination of candidates for appointment to the medical corps of the United States army, to fill existing vacancies. Any person desiring to present himself for examination by the board will make application to the secretary of war before October 1, 1898, for the necessary invitation, giving the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which he was graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal acquaintance, from at least two reputable persons, as to citizenship, character, and habits. The candidate must be between twenty-two and twenty-nine years of age, and a graduate from a regular medical college, as evidence of which, his diploma must be submitted to the board. Successful candidates at the coming examination will be given a course of instruction at the next session of the army medical school. Further information regarding the examinations may be obtained by addressing the surgeon-general, United States army, Washington, D. C.

The Maritime Medical Association held its eighth annual meeting in Halifax, N. S., on July 6 and 7, 1898, under the presidency of Dr. D. A. Campbell. The election resulted in the choice of the following officers: *President*, Dr. R. MacNeill, Stanley, P. E. I.; *Vice-Presidents*, Drs. G. A. B. Addy, St. John, N. B., W. B. Moore, Kentville, N. S., and S. R. Jenkins, Charlottetown, P. E. I.; *Secretary*, Dr. George M. Campbell, Halifax, N. S.; *Treasurer*, Dr. T. D. Walker, St. John, N. B.

The Spitting-Nuisance is by no means the peculiarly American institution that some of our home and foreign critics would fain have us believe. The trouble is quite acute in Paris, and the admonitions which have recently been posted up on the Seine boats and on the Paris omnibuses are treated as a dead letter. In order to induce people to desist from spitting in public places, the board of health has suggested that the public be instructed concerning the danger of this habit. The police prefect has therefore requested the boat and omnibus companies to add to the prohibition an appendix setting forth the reasons why it should be observed.

The Oregon State Medical Society.—At the twenty-fifth annual meeting of this society, held at Portland, June 2 and 3, 1898, the following officers were elected: *President*, Dr. C. H. Hall, of Salem; *Vice-President*, Dr. Harry Lane, of Portland; *Secretary*, Dr. William F. Amos, of Portland; *Treasurer*, Dr. M. H. Cardwell, of Portland. The next meeting will be held in Portland, June 15 and 16, 1899.

The Montana State Medical Association held its annual meeting at Missoula on May 25 and 26, 1898. The following officers were elected: *President*, Dr. B. F. Sandow, of Neihart; *First Vice-President*, Dr. J. J. Buckley, of Missoula; *Second Vice-President*, Dr. T. A. Grigg, of Butte; *Secretary*, Dr. B. C. Brooke, of Helena; *Treasurer*, Dr. G. H. Barbour, of Helena; *Corresponding Secretary and Historian*, Dr. O. Y. Warren, of Warm Springs. The next meeting will be held at Butte, on May 17, 1899.

A Society for the Study of Malaria.—It is proposed to establish a society in Italy for the study of malaria, and more especially of its prophylaxis. In the preliminary circular it is asserted that "malaria keeps 5,000,000 acres of ground in Italy from cultivation; it affects, more or less, 63 provinces and 2,823 communes; and every year it poisons about 2,000,000 inhabitants, killing 15,000 of them. It is impossible to estimate the economic damage done to our country by the scourge, and no sanitary problem is more intimately bound up with the question of our prosperity."

Dr. Joseph B. Bissell has been appointed visiting surgeon to Bellevue Hospital.

Rabies in Prussia.—The Prussian dog-muzzling regulations are very strictly enforced, but despite this act five deaths from rabies were reported in that country in 1897.

A Berlin Pasteur Institute.—A department for the treatment of hydrophobia by Pasteur's method, and for scientific research on the subject of hydrophobia, has just been opened in the Berlin Institute for Infectious Diseases. This establishment is the first of its kind in Germany.

Dr. George R. Elliott has been appointed orthopædic surgeon to the Montefiore Home for Chronic Invalids.

Professor Virchow is to deliver the Huxley lecture at Charing Cross Hospital, London, next month, and a dinner will be given in his honor. The dinner will take place at the Hotel Metropole, on Wednesday, October 5th. Lord Lister will preside.

Reviews and Notices.

STATISTICA SANITARIA DELL' ARMATA par gli Anni 1895 e 1896. Roma: Ludovico Cecchini. 1898.

THIS collection of sanitary statistics of the Italian navy for 1895 and 1896, published by the minister of marine, shows a great improvement in the health of the navy over preceding years. While for 1873 to 1892 the average sick rate was from 700 to 400 per 1,000, in 1895 and 1896 it was 375 and 354 per 1,000. There is also much of interest in the statistics concerning the prevalence of individual diseases, the institution of sanitary reforms, etc.

ENCYKLOPAEDIE DER THERAPIE. Herausgegeben von OSCAR LIEBREICH, Dr. Med., Geheimer Medicinalrath, o.ö. Professor der Heilmittellehre an der Friedrich-Wilhelms-Universität, unter Mitwirkung von MARTIN MENDELSOHN, Dr. Med., Privatdocent der inneren Medicin an der Friedrich-Wilhelms-Universität, und ARTHUR WÜRZBURG, Dr. Med., kgl. Sanitätsrath, Bibliothekar im kaiserlichen Gesundheitsamte. II. Band, 3 Abtheilung. Berlin: August Hirschwald. 1898.

THIS part of Liebreich's incomparable work carries on the subjects from Hydronephrose to Mammageschwülste, and includes such important titles as Hydrothorax, Hysterie, Idiotie, Ileus, Immunität, Intubation, Iod, Iodoform, Kalium, Karbolsäure, Kehlkopfkrankheiten, Kropf, Leberkrankheiten, Leukæmie, Lymphdrüsen, Magenkrankheiten, Malaria, and many others. The work is a marvel of thoroughness in the way in which it covers the entire field of therapeutics, and when completed will be a most valuable addition to the library of the German-reading practitioner.

A GUIDE TO THE CLINICAL EXAMINATION OF THE BLOOD FOR DIAGNOSTIC PURPOSES. By RICHARD C. CABOT, M.D. With Colored Plates and Engravings. Third Revised Edition. New York: William Wood and Company. 1898.

THE fact that the first edition of this work was published only twenty months ago is an evidence of the favorable judgment of the public, and the public is a better judge and a more nearly infallible one than any individual reviewer can ever hope to be, however good may be his intention. It is flattering to the reviewer, therefore, to see that this superior tribunal has sustained the opinion expressed by him upon the first appearance of Dr. Cabot's work. As an indication of the rapid strides which this comparatively new science of hæmatology is making, we note that the author's additions to the book include an account of Oliver's tintometer and hæmoglobinometer, new matter in the chapters on the primary anæmias and on leukæmia, and a description of Müller's "blood-dust" (the newly discovered constituent of normal and abnormal blood), seventeen hundred additional blood examinations, new observations on poisoning by alcohol, opium, corrosives, and ptomains, on aneurisms, on cretinism, and on paroxysmal hæmoglobinæmia. We know of no work in the English language of such a practical character as this, and certainly there is none in any language more recent.

NASAL OBSTRUCTION. The Diagnosis of the Various Conditions Causing it and their Treatment. By W. J. WALSHAM, M.B., C.M. Aberd., F.R.C.S. Lond. Illustrated. New York: William Wood and Company. 1898.

IN taking up a book of two hundred and fifty pages upon what is, after all, but a single symptom of nasal disease, one is apt to think that the matter has been overdone; but the great advance which has been made in recent years in our conception of the intranasal structures and of the nose itself as a physiological organ justifies the fullest possible study of those causes which may interfere with its proper functioning. This task Dr. Walsham has taken upon himself, and he must be congratulated on his success. He has long been a successful teacher of surgery and has brought to his task a valuable experience. He outlines his plan of preparing the present volume as "working from the known to the unknown —in other words, working from the known conditions of the parts, such as redness, swelling, etc., to the unknown disease of which they are the signs and symptoms, instead of first describing the disease and then discussing how it may be diagnosed from similar affections." As a result of this method, the statements appear in a tabulated form and in short paragraphs. A complete index makes it easy to find any particular subject, and this too in spite of the fact that the general topics of diagnosis and treatment are scattered through different parts of the volume. The author exhibits a familiarity with the very latest advances in this department of rhinology and shows on every page that he has been a careful student of its literature. Naturally such a volume contains little that is essentially new, but, when we consider how much undigested information there is in the average text-book, we are under obligations to any one who will arrange it in such a readable form as Dr. Walsham has done. We venture to say that any worker in this field, no matter how much he has read or how much he has done, will have his ideas clarified and his conclusions made more definite after perusing these pages. To the beginner in rhinology no better guide can be furnished.

ELECTRICITY IN DISEASES OF THE NOSE, THROAT, AND EAR. With 161 Illustrations. By W. SCHEPPEGRELL, M.D. New York: G. P. Putnam's Sons. 1898.

THIS work is to be commended from all points of view, for it is written in a fair and impartial spirit and frankly acknowledges the failure of electricity in certain respects, while extolling its value in others. The first five chapters are devoted to the physics of electricity, and special attention is given to the different methods of generating currents, with their varying physiological effects. Dr. Scheppegrell truly says that no physician can have satisfactory results with this therapeutic agent unless he fully understands its laws. It is not comparable to any drug which we can procure from the chemist in a far better condition than we could possibly prepare ourselves, but "in electro-therapeutics we are compelled very often to be the manufacturing chemist, distributing agent, druggist, and physician." Consequently we should know all about our remedy that it is possible to know. Chapters vi. to x. inclusive treat of methods of examination; then are discussed the special forms of application of the agent, such as cautery, electrolysis, cataphoresis, massage, etc.; the remaining part of the book is devoted to the special consideration of electricity as applied to the various diseased conditions suggested by the title. We must not forget to mention the fact that the X-rays receive full consideration from both the physical and the therapeutical point of view. Valuable features of the work are the elaborate bibliographical list, containing nearly six hundred references, and the excellent index.

ATLAS AND EPITOME OF OPERATIVE SURGERY. By DR. OTTO ZUCKERKANDL, Privatdocent in the University of Vienna. Authorized Translation from the German. Edited by J. CHALMERS DA COSTA, M.D., Clinical Professor of Surgery in Jefferson Medical College, Philadelphia, Surgeon to the Philadelphia Hospital, etc. Philadelphia: W. B. Saunders. 1898.

THE Lehmann series of hand atlases is acknowledged to be excellent. The superiority of colored plates and accurate illustrations over mere description, as a means of conveying a correct knowledge of the operations of modern surgery, is undeniable. In the book before us both the written matter and the illustrations are good.

LECTURES ON TUMORS. By JOHN B. HAMILTON, M.D., LL.D., Professor of Surgery, Rush Medical College and Chicago Polyclinic, Surgeon to Presbyterian Hospital, Consulting Surgeon to St. Joseph's Hospital, etc. Third Edition. Philadelphia: P. Blakiston's Son & Co.

THE last decennial revision of the nomenclature of the Royal College of Physicians took out of the list of tumors all the class due to infective organisms (the granulomata) and confined it strictly to the neoplasms and cysts. As the American Medical Association followed its lead, an entire re-arrangement of this book was necessary, and the work was improved by the suppression of at least one chapter. The sole regret of the reader of this book will be that the Royal College did not abolish tumors entirely.

CONSERVATIVE GYNECOLOGY AND ELECTO-THERAPEUTICS. A Practical Treatise on the Diseases of Women and their Treatment by Electricity. By G. BETTON MASSEY, M.D.; Physician to the Gynecologic Department of Howard Hospital and late Electro-Therapeutist to the Infirmary for Nervous Diseases; Fellow and ex-President of the American Electro-Therapeutic Association; Member of the Société Française d'Électrothérapie, American Medical Association, etc. Third Edition. Philadelphia.

New York, and Chicago: The F. A. Davis Company. 1898.

Owing to the preposterous claims put forward for the use and application of electricity by its professors, its progress has not been nearly so rapid as its undoubted merits have deserved, and for this reason the medical profession has fought shy of having recourse to this method of treatment. However, the scope and limits of electro-therapeutics are now more clearly defined, and in proportion as its claims have been brought within rational bounds, so has its use in medicine become largely extended. Dr. Massey's work, although not altogether free from the faults referred to above, is in the main an able exposition of the benefits to be derived from the treatment of diseases of women by electricity. The work is well got up in every respect, the illustrations being especially good.

Handbook for the Hospital Corps of the U. S. Army and State Military Forces. By Charles Smart, Deputy Surgeon-General, U.S.A. New York: William Wood and Company. 1898.

This, the third edition of Colonel Smart's well-known work, may be said to have been issued at a time when the hints contained in its pages on the duties of the hospital corps are particularly seasonable. The chapter on the "Sanitary Care of Camps" will at the present time appeal with more than ordinary force to the medical profession of this country. Colonel Smart says: "The site of a camp is of the first importance, because in the event of its insalubrity no exercise of care in the sanitary government can protect from evil consequences." And again, with regard to typhoid fever, he remarks: "The facts and arguments in favor of a soil origin of typhoid fever, were they even less convincing than they are, would have to be accepted by the military sanitary officer as offering the only sure basis on which to attempt the preservation of his command from the attacks of this disease." And he goes on to insist upon the need of active interference and supervision on the part of army doctors, in order that the soldiers' quarters may be erected in accordance with good sanitary principles. Colonel Smart's handbook should be part of the equipment of every military surgeon.

A Manual of Modern Surgery, General and Operative. By John Chalmers Da Costa, M.D.; Clinical Professor of Surgery, Jefferson Medical College, Philadelphia; Surgeon to the Philadelphia Hospital, etc. With 366 Illustrations. Philadelphia: W. B. Saunders. 1898.

This is a revised edition of Dr. Da Costa's useful manual of surgery. The revision has been attended with much success and the present production is in many respects an advance on its predecessor. The work throughout is notable for its conciseness; redundance of language and padding have been scrupulously avoided, while at the same time it contains a sufficient amount of information to fulfil the object aimed at by its author, namely, a text-book for the use of the student and busy practitioner. The sections relating to the surgery of the liver and gall bladder, the female breast, wounds inflicted by modern projectiles, electrical injuries, and the use of the Roentgen rays are in keeping with the remarkable progress made of late in these particular branches. The numerous illustrations are satisfactory.

Extra-Uterine Pregnancy.—Extra-uterine pregnancy is more frequent than is generally believed by most of the profession. When left to nature's resources the mortality is very high, the patient dying from primary hemorrhage, or secondarily from sepsis and peritonitis. The diagnosis is usually easy after the rupture takes place. The surgical mortality, in skilled hands, when the operation is done in time, is very low. No case of ruptured tubal pregnancy is out of danger until after a good ligature has secured the bleeding points. The abdominal route is the best and safest means of approach in these cases. Most cases should be irrigated properly, and drained after removal of the diseased tube and liberation of all adhesions. In all abdominal and pelvic diseases these cavities should be examined most carefully before making a diagnosis.—Cordier, *Annals of Gynecology and Pediatry.*

Clinical Department.

UNDIFFERENTIATED TROPICAL FEVERS.[1]

By A. Monje Lesser, M.D.,

Surgeon-in-Chief to the American National Red Cross Society, New York.

In regard to the fevers from which the patients suffered, some explanation should be made. I use the terms malaria and typhoid respectively, which terms doubtless cover a multitude of diseases. There were on the ship some typical cases of intermittent fever and typhoid fever. However, many suffered from a disease probably of malarial character, which I shall here describe, and which can be differentiated from other fevers of the tropics only by one with some experience.

The disease begins with a sudden rise of temperature, often to 105° and 106° F., and in two instances 107° F. The pulse runs up to from 100 to 130, but the respirations do not increase in rapidity proportionately. There are severe headache, circumorbital pain, pain in the neck, back, bones, and muscles. Nausea and vomiting accompany the fever. This condition (initiatory fever) lasts with but little remission for at least forty-eight, and often sixty-two hours; then the temperature begins to fall (usually in the morning of the third day, if carefully treated) to from 102° to 101° F. In the evening it may rise again and go as high as the day before, then falls during the night, with a profuse perspiration. The patient now feels comparatively well but weak. Some improve from that day, while others have exacerbations and remissions similar to those of intermittent fever, but there is no chill preceding the fever; instead the patient is nauseated and frequently vomits. Diarrhœa and other catarrhal troubles are complications from which the patient recovers as the fever leaves him. I found those cases on the ship especially among our convalescent yellow-fever patients.

I took specimens of blood for microscopic examination, but unfortunately not early enough in the attack, and after I had given quinine to the patient; so I do not know whether the absence of plasmodia would have any significance. However, the anæmia which existed was very marked, and the state of the blood was much the same as I found it in the reconcentrados in Cuba, who were sent from the interior high ground to the coast.

My treatment for these patients begins with a saline cathartic, and in some cases a washing of the stomach. To the irritable, if suffering from headache, I give one drop of the fluid extract, or, better, the normal liquid of gelsemium every half-hour until the first physiological symptoms appear, unless relief is obtained before; when mixed with two or three drops of water and placed on the tongue, it acts most quickly. (Gelsemium should not be given to the apathetic, or when the pupils are dilated and the face is pale.) When the temperature is lower I give 0.12 gm. (two grains) of quinine sulphate every two hours, with an equal quantity of dilute sulphuric acid. If the gelsemium has not given rise to any physiological symptoms, I continue to administer one or two drops with each dose of quinine. If the temperature rises again I discontinue the quinine, and continue the gelsemium hourly or half-hourly, as needed, but only while the fever lasts. The moment remission is fairly established, I begin again with quinine and the other remedies. The bowels should be kept clear by Epsom salts or Seidlitz powder, and I allow no food,

[1] An abstract from the report of the voyage of the transport *Concho*, submitted to Major Louis La Garde, Surgeon-in-Command of the Fifth Corps Reserve Hospital.

either solid or liquid, while the patient has a temperature above 101° F. I consider this of the greatest importance in order to insure positive action of the drugs. Water should be given, as much as possible, but it should be pure water. The cases thus treated get along best and without complications. The nausea and vomiting which preceded the paroxysm I have relieved by washing out the stomach, and this also somewhat assists in relieving the headache. A clear yellow fluid of alkaline reaction was returned from the stomach, with or without admixture of food. In cases in which I could not use the stomach tube I advised the patient to take two or three glasses of salt water and irritate his palate in order to produce vomiting. This usually gave great relief, even if only a portion of the water was returned.

For the diarrhœa, which often becomes troublesome, I give a mixture composed of one gram of pure carbolic acid, half a gram of tincture of opium, thirty grams of mucilage of acacia, and peppermint water enough to make one hundred and twenty-five grams, of which the patient takes a teaspoonful every two hours.

As soon as the acute symptoms have passed, one gram of sulphur, one decigram of camphor, and one-third of a drop of oil of peppermint should be given three times a day. After recovery great care must be taken in the diet until the strength is restored.

EXCISION OF THE BRACHIAL PLEXUS FOR NEURALGIA.

By WILLIAM W. BOSTWICK, M.D.,

ASSISTANT PHYSICIAN, SAILORS' SNUG HARBOR HOSPITAL, NEW BRIGHTON, RICHMOND, N. Y.

The comparative rarity of successful operations for the relief of intractable neuralgias of the brachial plexus leads me to report briefly the following case:

A. W. B——, an officer in the American merchant marine, suffered a dislocation of the right shoulder while at sea. No surgeon being on board, the luxation was unreduced till the vessel made port, a period of forty-two days, when by the heel in the axilla the head of the bone was replaced in the glenoid cavity. With what difficulty this was accomplished I am unable to say; at all events, the axillary artery was ruptured, gangrene set in, and the arm was amputated in the upper third.

Three weeks later the patient began to suffer from neuralgic pains of great intensity, and to complain of burning and tingling sensations referred to the fingers of the amputated member. Several operations were performed for the removal of bulbous enlarged nerves prior to his coming under our care.

In February last he was anæmic and worn out by his constant suffering, which medical treatment was powerless to relieve. On local examination the stump was found well-covered with healthy skin, but very tender, the tenderness extending to the region of the clavicle, scapula, and acromion process. From these indications of a degenerative process high up in the plexus, excision of the plexus was advised by Dr. W. C. Walser, although thickening and bulbous enlargements could be detected at the end of the stump.

The operation was performed on the 29th of February by Dr. Walser, assisted by Dr. Townsend and Drs. H. D. Joy and W. W. Bostwick of the hospital staff. The plexus was removed entire, leaving the origin of the long thoracic. A drain of silkworm gut was inserted, and the wound was closed by sutures of the same material. On the third day, the wound was inspected and being found healthy was redressed. On the fourth day, much to our disgust, the patient complained of pain starting in the neck in the line of incision and radiating to the root of the neck and shoulders. As his temperature was normal the wound was not inspected till the end of the first week, during which time the pain continued. On the seventh day during removal of the stitches a little puckering of the skin at the site of one of the sutures was noticed, which, when cut gave instant and complete relief, thus showing how trivial a matter may cause, in a neurotic individual, pain out of all proportion to that cause. From this on, the recovery was uneventful, and for the three months which have elapsed since the operation our patient has suffered no return of his neuralgia. His expression of constant pain has given way to one of cheerfulness, he has gained in flesh, and he claims to be a new man. Motor paralysis is complete, but sensation for touch and pain is preserved, and he describes sensations as if the "stump was asleep."

I have seen reports of the excision of the brachial plexus, and of the intradural section of spinal nerves, by Maury and Sands, Abbe, Horsley, Bennett, and McCosh, to the number of seven, of which three were unsatisfactory; in one case the man died on the eleventh day, and on autopsy sclerosis of the columns of Goll and of the posterior root zone was shown; and in three cases the results were more or less successful.

VICARIOUS MENSTRUATION.

By WILLIAM EDGAR DARNALL, M.D.,

ATLANTIC CITY, N. J.

I DESIRE to add the following case of vicarious menstruation to the interesting cases reported by Dr. Coughlin in the MEDICAL RECORD of June 4th:

Miss F. K——, white, aged twenty-three, unmarried, saleswoman, about a year ago was treated by me for gastric ulcer and anæmia, gaining in weight and color with the disappearance of all stomach symptoms, which have even yet never reappeared. Having gone to Virginia on a visit during the autumn, I was hastily summoned by a telegram, stating that she had had nine hemorrhages in one day from the stomach. When I arrived a day or two later, however, I found her up and about, and feeling very well. There was no evidence of anæmia, and she did not complain of pain or other stomach symptoms. The family had been much alarmed at the time of the hemorrhages; but I found on questioning her that they occurred just when a period was due, and that no normal menses had appeared, except a mere "show." She had been in a state of general discomfort for a day or so before, and she described her sensation when taken sick as "a rush of blood to the head." The natural plethora being relieved, she seemed to feel as well as usual after menstruation.

She is slight in build, but plump, blonde, and has never had any trouble with her uterine functions. Her menstruation has always been regular and normal. Several years ago she had some attacks of hæmatemesis while in very poor health. I attributed these, however, to ulcer, from the history she gave of them. It was impossible to find out whether they occurred at a menstrual period or in the intervals. Several months have elapsed since this attack of gastric menstruation without any further recurrence of it. She did not have at that time, nor has she had since, any symptoms of gastric ulcer.

1713 PACIFIC AVENUE.

Urethral Fever.—Five drops of oil of wintergreen six hours before and again immediately after a sound is passed will often prevent this trouble. Copious draughts of water should also be given to dilute the urine.—*International Journal of Surgery.*

Society Reports.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Fifteenth Annual Meeting, Held at Maplewood Hotel, near Bethlehem, N. H., August 31 and September 1, 1898.

First Day—Wednesday, August 31st.

Avenbrugger and Laennec.—Dr. E. O. Otis, of Boston, president of the association, delivered the annual address. After welcoming the members of the association, he entered upon the subject of his address, which was entitled "Avenbrugger and Laennec, the Discoverers of Percussion and Auscultation." It was quite improbable, he said, that an association largely devoted to the consideration of diseases of the chest would exist, were it not for the methods of thoracic examination which Avenbrugger and Laennec had discovered in auscultation and percussion; and it seemed eminently fitting that the society should honor the memory of these illustrious men by reviewing their lives and work. He then gave an account of Avenbrugger's life and his great work upon percussion, the "Novum Inventum." He was born in 1722, in Grätz, and died in Vienna in 1809; his discovery was given to the world in 1761. His life was spent in enthusiastic devotion to his profession and in love and service to his fellow-men. With dignity, sympathy, and enthusiasm in his art, modest, like most great men, never refusing to give of his best to suffering humanity, he richly lived out his long life. The "Novum Inventum" was neglected until forty-seven years later, when Corvisart revived it in 1808 by making a translation of it into French with copious commentaries, thus in truth making almost as great a discovery himself by discovering the original discovery. This work itself was discussed, with quotations from it, and its inestimable value shown. Corvisart, who translated the "Novum Inventum" of Avenbrugger, was also the teacher of Laennec, and thus by this happy coincidence united the two great discoverers, just as their discoveries were inseparably joined in practice. An account of Laennec's life was then given. He was born at Quimper, France, in 1781, and died at Plouaret in 1826. He published his immortal work on mediate auscultation in 1819. The incident leading to the discovery was narrated. One day while traversing the court of the Louvre, he perceived some children amusing themselves by applying the ear to the two extremities of a long beam or piece of wood, transmitting reciprocally the light sound arising from the blow of the finger against the opposite end. In the intermediate space no sound was perceptible. Laennec reflected upon this, and some days after, on being consulted by a young woman presenting the general symptoms of cardiac disease, with whom percussion was unsatisfactory on account of her stoutness and her age and sex, which prohibited the direct application of the ear to the chest, recalled the children in the court of the Louvre. Immediately he took a quire of paper and made a tight roll, one end of which he applied to the chest of the young girl and the other to his ear. With delight he found that in this way he perceived much more plainly the beating of the heart; and thus mediate auscultation was discovered. The development of the discovery and the making of the stethoscope were traced. Laennec's treatise upon "Mediate Auscultation and Diseases of the Lungs" was referred to, and its value emphasized. Laennec's whole life was absorbingly devoted to professional pursuits. He was absolutely true and unselfish in his professional aims. To improve his art, to seek truth in it wherever found, to establish the diagnosis of disease upon the sound basis of pathological anatomy and accurate observation, and to extend the knowledge of his new discovery—this was what he labored for. His courage in continuing his labors in weakness and suffering was heroic. In the diagnosis of diseases of the chest, he was universally admitted to be without a rival. Never robust, he wore himself out with his arduous labors as teacher, writer, and physician, and died of tuberculosis at the early age of forty-five years.

Common Errors of General Practitioners in Dealing with Cases of Pulmonary Tuberculosis.—Dr. Frederick I. Knight, of Boston, referred to certain common errors which he thought might be diminished if his remarks were indorsed by the members of the association in such a way as to give them the authority needed to influence the general profession. The errors to which he especially called attention were: (1) Failure to make an early diagnosis, which is now easy since the discovery of the tubercle bacillus. (2) Failure to admit the gravity of the situation the moment it is discovered, and to put the patient at once in the best possible condition for recovery. Niemeyer used to say that the danger of a consumptive patient was "that he became tuberculous." In the light of modern pathology Dr. Knight would say that the danger of a tuberculous patient was that he became consumptive, *i.e.*, the subject of secondary infection. There was often failure also to impress the patient with the gravity of the situation sufficiently to secure his thorough co-operation in the effort for his recovery. (3) Temporizing, giving nauseating medicines and too much alcohol, and prescribing exercises, etc., which only hasten the decline. (4) Sending patients away from home who have only a few months or weeks to live, or who have not sufficient money to live properly away from home long enough to do them any good; also exercising insufficient care in the selection of a residence for those who would probably be benefited by a change. (5) Insufficient professional supervision of patients, who always require constant watchfulness, whether they remain at home or go to some climatic resort.

The Result of Recent Experience with Phthisical Patients.—Dr. Vincent Y. Bowditch, of Boston, said that in his examination of patients he had been frequently impressed with the fact that one or two of what he believed to be the most important features in diagnosis, or rather prognosis, had apparently been overlooked by the physician in attendance. Although it was ordinarily comparatively easy to make a diagnosis of pulmonary tuberculous disease in cases in which dulness upon percussion, changes in the respiratory murmur, and even râles were lacking—cases in which the power of diagnosis and prognosis were taxed to the utmost—he had frequently found that the general practitioner had not paid sufficient attention to what he deemed the most important symptoms, the quality of the pulse, the temperature, and condition of the digestive organs. Post-mortem examinations had frequently shown that in patients with few physical signs in the chest, but with a weak, rapid pulse, more or less elevated temperature, and poor condition of the stomach, there had been an almost universal dissemination of tubercle, without perhaps marked breaking down of tissue. These unfavorable conditions of the pulse, temperature, and digestive organs he believed to be entirely inconsistent with a truly incipient form of tuberculous disease, even when the physical signs in the chest were few or entirely lacking. He referred to and emphasized his observations in a previous publication, entitled "A Plea for Moderation in our Statements Concerning the Contagiousness of Phthisis." While appreciating fully the teachings of bacteriology, the importance of absolute

cleanliness in connection with phthisical patients, and attention to the general health of those in attendance, he maintained that this care could be kindly and wisely given without causing a spirit of terrorism and without making such sweeping and unjustifiable statements as that "all homes for consumptives are a source of danger to the surrounding community." He mentioned the statement of Flügge, of Berlin, regarding the possibility of bacilli being carried in small droplets of mouth fluid into the air during the act of coughing, and believed that we should wait for further proof before accepting this extreme theory.

Dr. Didama, of New York State, referred to one of the errors mentioned by Dr. Knight, namely, that of sending to Colorado and elsewhere patients who were too far advanced in consumption, and he said it would seem that some physicians sent them away to escape signing the death certificate. Yet there were instances of patients who had had many hemorrhages having been benefited by a residence in Denver. He questioned whether, when the disease was far advanced and the patient was nervous about his condition, it was right to tell him frankly the absolute truth. Regarding the remedies, he said that consumptive patients were expected to improve as the medicine was changed or as they changed the doctor. Even within two or three days of death there was often an improvement in the symptoms under such circumstances. The speaker said he was glad Dr. Bowditch had spoken of the too common feeling that consumptives were social lepers. He did not believe there was any particular danger in having a friend call who had a consumption cough.

Dr. Walker, of Philadelphia, agreed heartily with the sentiments of both papers.

Dr. R. G. Curtin was much pleased with Dr. Knight's remarks in regard to the old-fashioned treatment of tuberculosis. He agreed with the remarks of Dr. Didama, that physicians were often to be blamed for sending patients away when they would be better at home, yet there were times when the advice was unheeded until the disease was too far advanced.

Dr. J. H. Musser, of Philadelphia, thought it one of the most difficult things in medicine to decide which cases should be sent away and which retained, and cited the case of a patient with apparent general tuberculous infection advanced to extreme weakness and emaciation whom he had advised to go to the Adirondacks. The patient's stay there under medical treatment had resulted in arrest of all manifestations of the disease.

Dr. Hart, of Denver, said that the papers of Drs. Knight and Bowditch expressed exactly what he had wanted to hear. He said that too often patients arrived in Denver in about the condition in which they were sent home, with every indication of advanced tuberculosis, and that it was avery difficult thing for the physician at the health resort to manage these cases.

Dr. Charles E. Quimby said that he had nothing to add personally, except that which Dr. Bowditch and Dr. Knight, through their kindness of heart, were prevented from saying, namely, that while their papers were ostensibly directed against certain errors of the general practitioner, they were intended for all, even for members of the association.

Dr. Coleman, although he had had few cases illustrating points brought out in the papers under discussion, believed that the early appreciation of the tuberculous lesion was the key to the cure, and that when a proper physical examination was made many of the errors would be avoided. It was the invariable rule of his life to make a thorough physical examination of all cases coming to him.

Dr. Beverley Robinson, of New York, said that, while he agreed with those who had spoken before, that a great many individuals were not examined carefully enough, that the diagnosis was not settled sufficiently soon, and that proper and judicious treatment was not followed up at all times as it should be, he believed that with a better understanding of the disease and the better education of the medical student this error would be much less frequently committed.

Dr. Knight said, in closing the discussion, that in the treatment of tuberculosis the excessive use of syrups should be avoided as much as possible.

Deaths in the Association.—Tributes were paid to the memory of Dr. Harrison Allen, of Philadelphia, by Dr. Curtin; of Dr. William Pepper, of Philadelphia, by Dr. Musser; and of Dr. T. D. Bratton, of Augusta, by Dr. Otis.

Ergot in Chronic Malaria.—Dr. A. Jacobi, of New York, read a paper with this title. He enumerated the active principles of ergot and the action of each. Ergot was very liable to lose its power in a short time, particularly when not gathered before the harvesting of rye, because of the speedy decomposition of its alkaloids and of its fat. After giving the result of his long experience with ergot in the treatment of malaria, Dr. Jacobi formulated the following conclusions: That there were cases of chronic intermittent fever with tumefaction of the spleen that, after having resisted the action of quinine, arsenic, methylene blue, eucalyptus, and piperin, were benefited by ergot. When enlargement of the spleen was not old and firmly established, the contracting effect of ergot was noticed within a reasonable time. The attacks would disappear before the diminution in the size of the spleen was very marked. Though the temperature after the employment of ergot remained irregular and was now and then somewhat elevated, chills as a rule were not noticed with this elevation. Plasmodia did not seem to disappear from the blood so rapidly as after quinine, when the latter was effective; even while some were still present, the attacks being more or less under control, the patient would feel better. Complicating local pain required additional treatment with ice or cold douches or heat; chronic hyperplasia demanded iodide of iron; digestive disturbances might indicate, as they often did when quinine was expected to act before the employment of ergot, an emetic or a purgative or stomachics. An experience extending over forty years, in which the speaker had used ergot in many instances, justified him in asserting at least this much: that there were many cases of apparently intractable chronic malaria that would get well with ergot. There were occasional cases in which the return of elevations of temperature after a successful use of ergot made the combination of ergot and quinine or of ergot and arsenic advisable, though quinine and arsenic had not been successful previously. Ergot, like quinine, probably by the sudden effect upon the spleen, was capable of bringing on the very first attack of chills and fever in chronic malarial poisoning when hydræmia and spleen tumors were not excessive.

The Distribution of Pulmonary Tuberculosis in New Jersey.—Dr. Guy Hinsdale, of Philadelphia, read a paper on this subject, and exhibited a map in which the various regions of the State were plotted so as to show the different degrees of prevalence of the disease. The distribution of tuberculosis in this State corresponded, he said, in great measure with well-known facts relating to the disease. Contrasted with New York and Pennsylvania, New Jersey did not show such wide variations. In the former State there were counties in which the disease was three or four times as rare as in equally densely populated districts. In New Jersey the counties in which the larger cities were situated showed a prevalence only twice as great as that of the sparsely settled regions.

Hudson, Essex, and Mercer counties, in which were situated Jersey City, Newark, and Trenton, had from four to five hundred persons living to one death from phthisis; while Sussex, Warren, Hunterton, and Gloucester counties had between eight and nine hundred persons living to one annual death from phthisis. The remaining counties were plotted to show the three intermediate grades. Elevation above tide, he thought, did not play a part, as it apparently did so plainly in the case of Pennsylvania. In New Jersey, on the other hand, one of the counties, Gloucester, in South Jersey, was quite low, but it belonged to the group in which tuberculosis was least prevalent. It was as free from the disease as were any of the most favored counties. In the northern and northwest part of New Jersey the surface was more diversified, reaching elevations of about two thousand feet. The soil of New Jersey was largely red clay with outcroppings in the northwestern part of sandstone, and in the northeastern portions of trap rock. In Essex county there were positive evidences of a great prehistoric lake, called Lake Passaic. Its southern portion was the present site of a great swamp. The soil of the southern half was principally sand, which in places like Lakewood reached a depth of six or seven hundred feet. But the character of the soil would seem to have little if any influence in the present instance in modifying the presence and distribution of tuberculosis. It was density of population which bore the closest relation to the distribution of tuberculosis in New Jersey. A diagram was shown in which this relation was characteristically represented. The counties which had less than one acre to each inhabitant had a high death rate from tuberculosis, while Atlantic, Sussex, and Cape May counties, which had from ten to twenty-two acres per inhabitant, had a low death rate. Three of these were maritime counties. Sussex had the lowest death rate of the four, and of all the counties in New Jersey it was the farthest from the sea and embraced the highest land in the State. It adjoined Pike County in Pennsylvania, one of the wildest and most healthful counties in that State. Few people visited the hilly country in the northern and northwestern portions. If they were more accessible to the larger cities, these undeveloped districts would no doubt be highly prized and largely sought.

A Plea for a Scientifically Accurate Method of Recording the Results of Physical Examinations of the Lungs.—Dr. Charles E. Quimby, of New York, read a paper with this title. This latter half of the nineteenth century had come to be known, no less in medicine than in other branches of science, as the age of progression. We as physicians might rejoice with peculiar satisfaction that in medicine the change had not been solely one of technique and application, but that in many lines at least we had started upon a strictly scientific basis. While surgery might perhaps present to the layman the most abstrusively attractive illustrations of exactitude in methods and results, the more critical and closely analytical professional mind must admit that the broadest and most potentially valuable advances in medical science of our own time had been in the domain of medicine. The very term, physical diagnosis, presupposed definiteness and certainty, claiming as it did for a basis the best developed of limited sciences. The purpose of this paper was to outline some modest attempts at recrystallization and to urge the adoption of a scientifically accurate method of recording the results of physical examinations of the lungs. That it was possible to make such a record, and in such manner as would render it a direct index to the amount of disease and a standard for future reference, the speaker was fully convinced. A complete physical record of respiration at any given point comprised (1) the pitch note of the trachea, (2) that of inspiration and expiration, and (3) the relative length of these two sounds expressed as a fraction. For example, respiration at point *a*, left chest: tracheal note, *g*; inspiration, *f*, above; expiration, *e*, between; rhythm, $^{3}/_{4}$. It was understood that the foregoing statements referred solely to respiratory sounds as affected by uniform changes in the chest and excluded localized excavations, although the same principles might be applied to these conditions. Thus respiratory with percussion sounds afforded an absolutely scientific, accurate record of pulmonary conditions and changes. It would be superfluous to dilate upon the value of such records in cases remaining under our own supervision, or for such as we desired to send to other climates and places in the care of other physicians.

Second Day—Thursday, September 1st.

A Case of Dissecting Aneurism of the Thoracic Aorta Rupturing into the Pericardial Sac and Causing Immediate Death.—Dr. Judson Daland, of Philadelphia, read the paper. He said that the rarity and completeness of this lesion, the evidences of perfect reparation of a similar lesion above the former one, and the extraordinary changes in the heart and aortic valves, together with the unusual mode of death, led him to call attention to a case, which he described in detail. The patient was a man, thirty-eight years old. The personal and family histories were unimportant except that he used whiskey moderately. He sought relief from œdema of the legs, headache, and diarrhœa. His symptoms improved under absolute rest, eight ounces of buttermilk every two hours, and Basham's mixture. He gradually resumed a mixed diet, and did not again seek medical aid for four years. During this interval he returned to the use of whiskey, averaging two pints a day. Examination showed marked arterio-capillary fibrosis and considerable increase of hypertrophy of the left heart with a faint systolic murmur. Two years previously he had suddenly experienced complete loss of muscular power without other symptoms. The urine presented a moderate amount of albumin and a few hyaline tube casts. Three months later he complained of excessive muscular weakness and fear of death, accompanied by headache and morning vomiting. In a few weeks he suddenly developed left hydrothorax with excessive frequency and irregularity of breathing, rapid and irregular heart action, and cyanosis, which were relieved by thoracentesis. Five years after the first examination ordinary evidences of cardiac failure showed themselves and he died suddenly in December of the same year, apparently from cardiac failure. The diagnosis was marked arterio-capillary fibrosis, enormous left ventricular hypertrophy and dilatation, with mitral regurgitation and chronic interstitial nephritis alcoholica. The autopsy showed, one-half inch above a recent rupture of the aorta, a linear spot measuring one-half inch in length and parallel to the long diameter of the artery. It communicated directly with the pericardial sac and was the immediate cause of death. There was evidence that the dissecting aneurism extended for an unknown distance into the thoracic aorta.

Clinical Notes on Asthma and its Treatment.—Dr. Beverley Robinson, of New York, read a paper with this title. He said:

"Among the diseases which the practitioner is called upon to treat, none is of greater interest than asthma. This interest is partly due to its etiological obscurity. The cases of so-called nervous asthma in my experience have been infrequent, and I believe that when we are better informed examples of purely functional asthma will be perhaps no longer described. I believe that despite the existing nervous irritability the

asthmatic attack would rarely occur, were there not other discernible cause, which more advanced researches will reveal. Conditions of the blood are often ignored. Malarial toxæmia is frequently present and yet overlooked. It is wisdom to act in accord with its recognition. If there be sudden chill followed by rise of temperature and sweating, and if at the time of the chill and previous to the giving of quinine internally a skilful microscopic blood examination be made, the plasmodium malariæ should be found. For an asthmatic attack of probable malarial causation I advise increasing doses of Fowler's solution of arsenic to its physiological effect; if the bowels are constipated and the liver is inactive, Warburg's extract in five-grain doses three or four times daily; if anæmia be present, quinine, iron, and arsenic in a suitably formulated pill, the following being a favorite with me: One grain of reduced iron, two grains of sulphate or preferably the muriate of quinine, and one-sixtieth to one-thirtieth of a grain of arsenious acid, three times daily after meals. Of course, if the attack be severe, we should employ antispasmodic remedies, and also permit patients to smoke and inhale from a cigarette d'Aspic, of datura tatula, or of simple nitre paper. As a last resort, an inhalation of a small quantity of chloroform or a hypodermic of morphine and atropine may become our only satisfactory help.

"I am in accord with those who find in the constitutional conditions of gout and rheumatism an underlying influence of great power in causing nervous irritability and characteristic appearances of the throat, and when we have a clear history of these affections we may infer many times that the asthmatic attack is of similar origin.

"As to the reflex causes of asthma, when we find in the nose and throat morbid conditions we cannot be satisfied with our care of the patient unless operative interference be undertaken to modify or remove these evidences of disease. While this is true, it should be admitted that several prominent throat specialists have exaggerated the diseased conditions of the throat and nose as causative in producing asthmatic attacks.

"In chronic gastric catarrh, brought on by errors of diet or alcoholic habits, frequent lavage of the stomach and a regulated regimen have afforded great relief in the asthmatic seizures.

"In the consideration of bronchitic cases of asthma with some development of emphysema we are confronted with questions clinically most difficult to decide. When the bronchitis is clearly defined and the secretion slight our main effort should be to stimulate the latter by appropriate means, and here I find small repeated doses of ipecac, tartar emetic, grindelia robusta, chloride of ammonium, and iodide of potassium very useful. When the bronchitis is also evident and yet there is much bronchial secretion, belladonna or atropine must be combined in small or moderate doses with the drugs previously named, or be given with a little camphor and quinine in capsule or tablet form, or, what is often preferable, alone, until their physiological effect is manifest. When the emphysema and bronchitis are clearly defined and when the asthma is also pronounced we must have recourse for temporary results to inhalation of the fumes of the antispasmodic cigarettes, the repeated use of oxygen gas, administration of Hoffman's anodyne, alcohol, hot coffee, capsules of ether or chloroform.

"When in connection with the previous conditions we have evident cardiac distention, we must recur to the use of nitroglycerin or the nitrites, or to a soluble salt of caffeine (salicylate), either by the mouth or hypodermically. Occasionally blood letting by bleeding from the arm, or the use of leeches or wet cups to the chest or epigastrium, will afford more or less lasting relief. Usually, I regret to say, the relief is only temporary, and it is under these circumstances that particular care must be taken in the use of amyl nitrite in inhalations, which seem to occasion further and more intense pulmonary congestion, and thus add another obstacle in front of a right heart already overtaxed.

"One of the most difficult matters to decide is when and how frequently we should give morphine injections hypodermically. I am compelled to counsel great care in its use.

"The question of change of locality is one difficult to solve. Personally, I am inclined to believe, after considerable experience, that the climatic conditions which shall prove best for subacute or chronic bronchitis are also those best suited to the bronchitis when complicated with asthma."

Sanatoria and Special Hospitals for Poor Consumptives and Persons with Slight Means.—Dr. J. M. Anders, of Philadelphia, summed up the more salient points and inferences brought forward in a paper with this title, under two heads: (*a*) Those that show the extent and urgency of the needs presented by the large class of phthisis patients, and the value of special hospitals and sanatoria for their treatment. (*b*) Points bearing upon the discrimination of the cases among the lower class into three groups, and the remedy—an institution with distinctive characteristics—for each.

Under the first head the author stated: (1) That the adduced statistics proved that pulmonary tuberculosis was proportionately far more common and more inauspicious among the lower than among the higher classes. (2) That the almost absolute lack of proper facilities for the poor afflicted with pulmonary tuberculosis, as shown by the tables given, was a most potent factor in maintaining the enormous death rate from this disease. (3) That special hospitals, in which every hygienic detail could be arranged with precision, were superior to separate wards in general hospitals for the treatment of cases of pulmonary phthisis. (4) That the admission to and care of such patients in the wards of general hospitals, with those suffering from other forms of illness, was to be energetically deprecated, owing to the serious danger of transmitting the disease, particularly during the breaking-down period. (5) That the mortality figures showed a reduction of fifty per cent. in consequence of the operation of special hospitals for consumptives (*e.g.*, city of London). (6) That sanatoria near large cities afforded better advantages than the so-called special hospitals in densely populated centres, while climatic sanatoria, if properly situated, officered, and equipped, showed results surpassing those of all other known methods of treatment in the earlier stages of the disease. (7) That sanatoria lessened the mortality rate of phthisis in communities in which they were situated.

Under the second heading the author considered the cases under the following groups: (1) The numerous cases that had progressed to an advanced and practically hopeless stage. These required every comfort such as could be furnished in a healthful urban locality by special hospitals for consumption. (2) Incipient cases among the pauper element—the true wards—of society. For such, sanatoriums conveniently located in close proximity to large municipalities, though with special reference to such factors as purity of atmosphere and protection by natural elevations or woodland from chilly blasts, should be provided. (3) Phthisis pulmonalis among the middle class and working-class, or persons having small means. The members of this group would find themselves compelled to depend principally upon private philanthropy and probably semi-State institutions, and needed institution treatment in the best climates. The

writer saw no reason why the combined sanatorium and climatic treatment should not be attempted, since such an undertaking could be made to be almost self-sustaining.

Infection from the Hands in Phthisis.—Dr. E. L. Baldwin, of Saranac Lake, read a paper with this title. The paper described the results of an examination of the hands of twenty-eight patients by washing their fingers in a sterilized weak alkaline solution. Inoculation of the washings into guinea-pigs was successful in producing tuberculosis from ten out of fifteen patients, mostly in advanced stages of the disease, and many of whom expectorated into handkerchiefs. Out of twenty-four cases in which the centrifugalized washings were examined microscopically for bacilli, six were positive. The author regarded the danger of infection from the hands as small unless it could be shown that the disease was more frequently acquired through the mouth, but urged more general use of cheap destructible handkerchiefs, and frequent ablution, where cuspidors were impracticable.

The Value of Systematic Physical Training in the Prevention and Cure of Pulmonary Tuberculosis.—Dr. E. Fletcher Ingals, of Chicago, in a paper with this title said that the absence of systematic study by physicians and the very meagre literature compelled him to be somewhat dogmatic in his paper. One of the most common observations made by medical men, he said, was that the long, narrow, flat-chested individual was the one liable to the development of tuberculosis; and that in patients presenting this form of chest the chances for recovery were reduced to a minimum. This observation he considered sufficient to suggest that systematic physical training in aiding the development of the respiratory muscles, thoracic walls, and pulmonary capacity would be of great service in preventing tuberculosis and in curing its early stages. Collapsed air cells, he said, furnished a most favorable nidus for the development of tuberculosis; therefore, for the prevention of the disease, measures should be adopted to expand the lungs and bring the air cells into the best possible working condition. He thought it probable that in most cases there was an early tuberculous localized anæmia, diminishing the nutrition of the parts and making them more susceptible to the tubercle bacilli and their toxins. Of the large percentage of the human family said to be affected by tuberculosis (eighty per cent.), the majority recovered, even when the disease affected the lungs, it not proving fatal in more than twelve per cent. He stated that in most of those who recovered the disease had made but little progress, and that it was only at autopsy after death from other causes that its presence was detected, in view of which it was the physician's duty to recommend measures likely to strengthen the resisting power of the lungs. The beneficial influence of a high altitude he considered probably due to the increased distention of the air vessels, and that as a means of prophylaxis the first measure should be to teach the patient to breathe deeply. Careful physical training, he said, was of the greatest importance, it being possible for the long, narrow, flat-chested to increase the expansion of the chest two or three inches, improve the form, and increase the circumference. He believed it possible by physical development to check the process of tuberculosis when it had become established in the chest and to promote recovery.

A Single Test of the Virulence of Sputum Kept Many Months.—Dr. Irwin H. Hance, of Lakewood, N. J., referred to the virulence of the tubercle bacilli as demonstrated by the clinical pictures of pulmonary tuberculosis and the resistance of the germs of the disease. He described the experiment of Stone in 1891, in which the tubercle bacilli retained their form and virulence for three years. Similar experiments made by himself were described, with results so different as to justify the conclusion that the tubercle bacilli were no longer viable. The following queries were presented: Whether sputum which remained in a liquid state for a long time developed toxins inimical to the life of the tubercle bacilli; whether the result would not have been different had the sputum been more virulent in its character, and taken from a case of acute active tuberculosis; whether if sputum dried more rapidly it retained its virulence longer. All such queries he believed could be answered only by further experimental work.

Some Statistics of Orrhotherapy in Tuberculosis.—Dr. J. E. Stubbert, of Liberty, N. Y., gave a short history of experiments in antitubercle serum, dating back as far as 1890. He referred to the work of Bernheim, Bertini, Coupard, St. Hilaire, Haricourt, de Schweinitz, Maragliano, and Babes. The theory of action and the method of preparation were given. The action of the tubercle serum was not a germicidal one, but it attacked the disease indirectly by destroying the pabulum upon which the germ throve. He showed that de Schweinitz had succeeded in producing a partial immunity or an artificial resistance in guinea-pigs. Antitoxic serum developed from horses was more effective than that from other animals. He believed that the amount of clinical evidence was not sufficient to justify credence in the good results claimed for different serums. He gave the results of eighty-two cases in all stages of the disease treated with serum. The use of the serum was indicated only in incipient cases, although in the advanced stage temporary reduction of temperature had been obtained in a few instances. The use of the serum was, generally speaking, contraindicated in far-advanced cases showing signs of softening; in incipient cases with marked hereditary taint; in patients whose corpulence and vital capacity were much below the normal standard and who showed rapid heart action; and in cases showing mixed infection. He had used the antistreptococcic serum to reduce cases of mixed infection to those of simple, that the antitubercle serum might act more freely. His experience in this, however, had been insufficient for definite conclusions. He asserted that no danger attended the injection of the serum, and claimed as an advantage the absence of interference with digestion. In cases in which the bacilli had disappeared, this disappearance occurred while the sputum was still present. To the present time there had been no relapses among patients declared cured, even in patients returned to former environments. The writer did not declare himself a thorough advocate of orrhotherapy, adhering still to climatic, hygienic, and dietetic treatment in all cases, but believed that sufficiently good results had been obtained to justify further research in the same direction, better pursued in sanatoriums. He gave the following table of cases treated with serum: Number of cases treated, 82; expectoration decreased in 82 per cent.; appetite improved in 81 per cent.; weight gained in 78 per cent.; physical signs improved in 82 per cent.; temperature decreased in 49 per cent.; bacilli disappeared in 13 per cent.; apparent immunity established in 21 per cent.; bacilli decreased in 35 per cent.; cough decreased in 79 per cent.; generally improved, 85 per cent.

Pretuberculous Stage of Phthisis, or the Condition which Antedates Tuberculous Development, and Some Aid to its Diagnosis.—Dr. Henry P. Loomis, in a paper with this title, described a condition precedent to the initial development of tuberculosis, which should be called the pretuberculous stage, the signs of which were to be looked for in corpulence of the individual—*i.e.*, the relation of the weight ex-

pressed in pounds to the height expressed in feet; in the conformation of the chest, chest measurements, and vital capacity; in the constitutional condition—that is, whether or not there be a chloro-anæmia; in digestive disturbances; and in the character of the pulse. Progressive loss of weight without apparent cause was an indication of this pretuberculous stage. Out of forty cases of which very complete records had been kept, the writer had noted this characteristic loss of weight in fifty per cent. Vital capacity did not indicate anything special, but taken in connection with the height was an important aid. The normal vital capacity of a man of five feet eight inches was two hundred and thirty cubic inches. The relation between height and vital capacity for the normally healthy man was one to three; that of a woman, two to six. The writer believed chloro-anæmia to be one of the most pronounced symptoms of the pretuberculous stage, especially when taken in connection with loss of weight without cause and poor chest development. In these cases the hæmoglobin was diminished out of all proportion to the loss of the number of red corpuscles. There was a relative feebleness of arterial pressure in the pretuberculous stage.

Application of the X-Rays in the Diagnosis of Tuberculosis.—Dr. Francis H. Williams, of Boston, presented a general statement of the medical applications of the *x*-rays. One of its most useful applications, he said, was for diseases in or contiguous to the thoracic cavity, and in that connection he considered the subject. Diagrams were shown, which were made by transferring outlines, which the author while looking through the fluoroscope had drawn on the skin of patients, to a skeleton outline copied from one of Luschka's plates. The position of the diaphragm and heart in full inspiration was shown, and the position in expiration. In health it was seen that the diaphragm had a wide excursion between the extremes of respiration and that the heart also changed its place. The difference in the brightness of the lung area between expiration and full inspiration might be perceived in the fluoroscope. This showed how conditions involving congestion, as in early tuberculosis or in some form of cardiac disease, might alter the appearances in the fluoroscope. The diagram of health was used as a key to the others and comparisons were made with it and the diagrams of the various diseases. Thoracic aneurisms might now, he said, be recognized with certainty; further symptoms due to aneurism were sometimes ascribed to other diseases, and an *x*-ray examination was required to establish the diagnosis. Diagrams were exhibited, showing the excursions of the diaphragm, the position of the heart, and the appearances in emphysema, pleurisy, pneumonia, pulmonary tuberculosis, pneumohydrothorax, and pneumothorax. The author was convinced that as the *x*-ray examinations in pulmonary tuberculosis came more into use, the presence of the disease would be recognized earlier. A number of cases were cited to illustrate some of the ways in which *x*-ray examinations might be useful in pulmonary tuberculosis.

Officers.—The following are the newly elected officers of the association for 1899: *President*, Dr. Beverley Robinson, New York; *Vice-Presidents*, Drs. James A. Hart, Colorado Springs, and R. C. Newton, Montclair, N. J.; *Secretary and Treasurer*, Dr. Guy Hinsdale, Philadelphia; *Council*, Drs. Isaac Hull Platt, Lakewood; S. C. Solly, Colorado Springs: James B. Walker, Philadelphia; E. Fletcher Ingals, Chicago; and E. O. Otis, Boston; *Delegate to the Executive Committee of the Congress of American Physicians and Surgeons*, Dr. F. I. Knight, Boston; *Alternate*, Dr. Roland G. Curtin, Philadelphia.

The association adjourned to meet in New York City in May, 1899.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

A HEAT WAVE—A QUARTER'S MORTALITY—VACCINATION ACT—HOSPITAL STUDENTS AND MIDWIFERY—REPORT OF ASYLUMS BOARD—JENNER INSTITUTE OF PREVENTIVE MEDICINE—PHARMACEUTICAL CONFERENCE—A SAD MISTAKE—GOLDER'S HILL—DEATHS.

London, August 19, 1898.

The weather has held to its right as the one topic of Englishmen. We have had a hot wave for a few days; not such as, perhaps, New York would consider extreme, but one to prostrate Londoners. Anything over 80° F. is to us hot, and when the thermometer approaches 90° F. we give up. On Tuesday we had a thunderstorm with heavy rain in the small hours of the morning, and got up in a much cooler atmosphere. The day, indeed, gave us a fall of four degrees. There were still, however, many cases of sunstroke and collapse from the heat; as many as two hundred were treated in three days at the hospitals. Thunderstorms have also prevailed in the provinces, and the heavy rains have caused great damage to the corn crops. Doctors are busy with diarrhœa and various summer diseases, as well as the more sudden effects of heat. The meteorologists report no signs of a break-up at present, so we may anticipate a warm autumn.

The registrar-general's report for the quarter ending June 30th has appeared, and shows an annual death rate of 16.2 per 1,000 of the estimated population, which is 1.7 below the rate in the corresponding quarters of the preceding ten years. This is lower, with one exception, than the second quarter of any year recorded.

In the urban population, estimated at 21,500,000, the rate of mortality was 16.6 per 1,000. In the rural population of nearly 10,000,000, the rate was 15.4. These rates are below the corresponding quarters for ten years by 1.9 and 1.3 respectively. The mortality from the chief zymotic diseases was 0.20 below the average of the decennium. The rate of infant mortality, *i.e.*, the proportion of deaths of those under one year to the registered births was 123 per 1,000 for England and Wales; in London it was 127, and in the 32 large towns it reached 136.

The vaccination act has received the royal assent, and, though it will not come into full working until January 1st, the conscience clause is to operate immediately, so that the voluntary plan is now law. Surprise is expressed at the support given in the house of commons by the medical members, and many are asserting that these gentlemen by no means represent the opinions of the profession. It seems a great pity that such a question should be in any way regarded as a party one, and the way in which many Conservatives refused to follow the government in this matter is deserving of all praise. In the upper house Lord Lister's speech was listened to with great respect, and though he accepted the act rather than delay legislation, he did so on the intimation that a revaccination bill was to be proposed next year. This it was, he said, which led him "to acquiesce in what he regarded as a tremendous experiment."

The home secretary, in reply to questions in the house of commons, has promised to make a full inquiry as to the supply of hospital students to attend poor women in their confinements. It was insinuated that the hospitals sent students who had never seen a case to take charge, without any intimation that they were not qualified, although the General Medical Council did not permit private practitioners to act

thus. I believe the questions were misleading, and though students go from the hospitals qualified help is always ready, and in first cases there is close superintendence. We shall see what the council has to reply to the home secretary, who was also desired to ask whether members of the council were not themselves connected with hospitals which supplied students, and whether the privy council would compel the council to enforce its own regulations.

The report of the asylums' board contains many important facts. The admissions in 1897 were 58.5 per cent. of the cases notified, which is in excess of previous years. Out of 15,115 scarlet-fever cases the mortality was 4.06 per cent., as against 4.2 in 1896. The fatality rate of diphtheria was the lowest reported, 17.4 per cent.; enteric-fever mortality was 18.7, an increase of 2.5 over the previous year. Out of 70 cases of small-pox admitted, 13 died.

There are generally cases of erroneous diagnosis in these reports, and they do not seem to diminish. No less than 5.3 per cent. of the cases admitted had been erroneously diagnosed. This is particularly noticeable in small-pox. Out of 121 cases sent for this disease, 52 were not such. Happily they were intercepted at the wharves and so did not reach the ships. It looks as if the appearances of small-pox were not at all familiar in general practice. With the advent of voluntary vaccination, practitioners will need to be more careful.

You may remember that in 1896, the centenary of Jenner's great discovery, a movement was started for commemorating the event by inaugurating a work of national utility in honor of Jenner. The jubilee and Lord Lister's illness combined to postpone decisive action, though it was proposed to raise a subscription for the purpose in connection with the Institute of Preventive Medicine, which is established to carry on researches in the field in which Jenner was a pioneer. It is now determined that the institute shall in the future be named the "Jenner Institute of Preventive Medicine," and thoroughly to equip it as a national memorial a sum of £100,000 is proposed to be raised. About £8,000 has been promised by four or five leading men, and it is hoped that the whole sum will be forthcoming.

The Pharmaceutical Conference met at Belfast, August 9th, 10th, and 11th, and had a warm reception from the corporation and Queens College. Dr. Symes was president, and in his address urged the necessity of education to advance pharmacy, and showed that the conference encouraged men to devote themselves to the higher branches of their calling, and keep all posted in the advances that are constantly being made. The new "Pharmacopœia," though adversely criticised by many pharmacists, he thought largely represented the advances made since the last issue; but he regretted that there were no pharmacists on the committee, and that the manner of publication had led to uncertainty and inconvenience at first. Interesting papers followed and were continued the next day. The third day was almost entirely given up to the "Pharmacopœia," and useful papers and discussions on the new authority could not but prove valuable. There was plenty of sound criticism, though it was generally admitted that the new issue was an advance on the last.

At one of our children's hospitals a painful mistake has been made in returning the body of a wrong child for burial. The mistake was not discovered until the body had been in the supposed parents' house four days. It is not so long since the similar error in one of our asylums board's institutions occurred. It seems that some additional precautions are required to prevent such unfortunate mistakes, which cannot fail to give pain to those concerned and produce a very unfavorable impression of the management.

The beautiful estate of Golder's Hill, Hampstead, which is identified with the late Sir Spencer Wells, has been saved from the speculating builder, and will be handed over to the county council for the benefit of the public.

The first English funeral at Wei-Hai-Wei was that of a distinguished medical officer, Fleet-Surgeon Charles A. Macaulay, who died on June 15th. He entered the navy in 1875, saw a good deal of service in Egypt, for which he held the medal with Alexandria and Tel-el-Kebir clasps. He also received the Medjidie, fourth class, and the Khedive's bronze star. He attained the rank of fleet surgeon in 1896.

Mr. J. L. Milton, M.R.C.S., died on the 3d inst. He was for many years surgeon to that unfortunate institution, St. John's Hospital for Skin Diseases, and took part in its management or mismanagement. He wrote some brochures on the skin, but his chief literary effort was extraprofessional—"The Stream of History."

THE NEW ARMY TREATMENT OF TYPHOID FEVER.

To the Editor of the Medical Record.

Sir: The new army treatment of typhoid fever by recommending thousand-mile railroad jaunts is so unique that I think the profession should be given the details of such cases. We know that some diseases are benefited by travel, but trips from, say, Long Island to Michigan or Chickamauga to New York, have not heretofore been tried upon a large scale for enteric fever. I went through the wards of the Bellevue and the Presbyterian Hospitals on September 5th, and selected the following cases, in which the diagnosis of typhoid fever has been established in each instance by the presence of the Widal reaction, and the symptoms of rose rash, enlarged spleen, a temperature exceeding 104° or 105° F., a dry brown tongue, and typical facies —symptoms which (as we are in the habit of teaching second-year medical students) are rarely seen earlier than the second week of the disease. All cases presenting the least doubt I carefully excluded, and most of those here reported were from their history and appearance without question well advanced upon admission in the second and third week of the disease. I might present a much larger list of cases of malarial fever received at these hospitals in an equally serious condition (one patient who had pernicious malaria with purpura has just died within three or four days of shipment), but I prefer to focus the report upon typhoid fever. It should be observed that Camp Wikoff is about four hours by rail from New York, that at the camp the distance from the tents to the station is from one to two or more miles over one of the dustiest roads ever seen, and, finally, that the Red Cross relief station at Long Island City picks up the exhausted soldiers from the trains as they are dumped from the cars, succors them, and distributes them in ambulances to the overcrowded hospitals of New York. In each of the following cases the plasmodium malariæ was absent and the Widal reaction was strong:

Presbyterian Hospital.

1. R. P. O'L.—Twelfth United States infantry; received August 30th; temperature on admission, 105° F.; pulse, 128; shipped direct from quarters at Camp Wikoff to New York on one month furlough.

2. William D.—Sixth United States cavalry; received September 2d; temperature on admission, 104.8° F.; well-marked rose rash, etc.; shipped from Camp Wikoff for Philadelphia on thirty days furlough; rode his horse between camp and train, between two

and three miles; nearly fell off his horse before arrival; asked why he didn't go to the camp hospital, said there were too many dying there; food on train, biscuits.

3. O. L.—Thirty-third Michigan; admitted September 2d; temperature on admission, 105° F.; shipped from quarters at Camp Wikoff for Michigan with his regiment; ate bananas on the train.

4. Charles H.—Thirty-fourth Michigan; admitted September 2d; temperature two days later, 106° F.; shipped from Camp Wikoff with his regiment for Michigan; picked up at Long Island City.

5. Louis E.—Thirty-fourth Michigan; admitted September 4th; temperature on admission, 104.2° F.; abundant rose rash, etc.; shipped from the camp with his regiment for Michigan; picked up in Long Island City; had refused to go to the camp hospital.

6. A. M.—Thirty-fourth Michigan; admitted September 3d; temperature on admission, 104.8° F.; had been ill six weeks; had refused to go to the camp hospital; shipped from quarters at Camp Wikoff with his regiment for Michigan.

7. H. S.—Tenth United States infantry; received September 2d; temperature on admission, 104.5° F.; pulse, 108; had refused to go to the camp hospital; was shipped from his quarters at Camp Wikoff for Virginia on furlough; walked part of the way from camp to train.

8. R.—Thirty-third Michigan; admitted September 2d; temperature on admission, 105.5° F.; pulse, 108; delirious.

9. C. L.—Twelfth New York; received August 27th; temperature on admission, 102.6° F.; abundant rose rash; shipped from Chickamauga to New York.

10. Norman P.—Thirty-fourth Michigan; received September 2d; temperature on admission, 105.5° F.; had been on "sick call" in the general camp and had been given medicine; shipped from quarters at Camp Wikoff with his regiment for Michigan; picked up in Long Island City; referring to railroad trip, said: "That ride just done me up."

11. W. Van F.—Seventy-first New York; admitted August 20th; temperature on admission, 103.5° F.; pulse, 112; respirations, 30; had refused to enter camp hospital; shipped direct from quarters for New York; said a lady gave him some milk on the train; walked into the Presbyterian Hospital.

12. William H. F.—Seventy-first New York; admitted September 2d; temperature on admission, 104.5° F.; shipped from quarters at Camp Wikoff to New York.

13. George B.—Twelfth New York; admitted August 27th; temperature on admission, 104° F.; shipped from Chickamauga to New York, having been ten weeks in the camp hospital.

14. William B.—Admitted August 27th; temperature on admission, 102.3° F.; sent from Chickamauga to New York on one month furlough; in third or fourth week of disease, unquestionably; said he had been one week in the regular hospital at Chickamauga.

Bellevue.

15. James E.—Tenth United States infantry; admitted August 31st; temperature on admission, 105° F.; shipped from quarters at Camp Wikoff for Rochester on ten days furlough; walked from camp to train about two miles; fed before starting; no food on train.

16. C. B.—Thirty-third Michigan; admitted August 31st; temperature on admission, 105.2° F.; abundant rose rash; shipped direct from quarters at Camp Wikoff for Michigan on thirty days furlough; walked a mile to the train; had no food on the train.

17. George M. D.—Ninth New York; admitted August 24th; temperature on admission, 105° F.; abundant rose rash, etc.; shipped from Chickamauga to New York on thirty days furlough; food on train mainly steak and eggs.

It will be noticed that not a single case from Camp Wikoff had been in hospital there, all the patients having come from "quarters" or the general camps, where they had been mingling freely with the well men, and using latrines distributed all over Montauk Point, the patients being from so many different regiments. It follows, therefore, that the entire camp is hopelessly infected. During a personal visit to Camp Wikoff on September 2d, in company with a very well-known New York physician, we saw standing outside of a pavillion, which the army surgeons told me contained many of their worst cases of typhoid fever, a large tin ash barrel, in which I both saw and smelled a mass of typical "pea-soup" dejecta, fully six inches in depth, wholly uncovered except by flies. On my return a couple of hours later it was still there, still uncovered, still full of active flies. Meals were being served a few rods distant. After talking with the nurses and surgeons in the fever hospital I was convinced that the methods of disinfection there were obsolete, inefficient, and farcical. I could give many other examples of reckless disregard of elementary hygiene.

A patient having six or a dozen diarrhœal enteric stools a day, using the ordinary closet of a railroad car travelling, say, thirty miles an hour, distributes a trail of fæces along the track, to be washed by the first rain into neighboring streams, and sets a rather bad example of hygiene to the country at large.

The universal infection of our home camps in time of peace with one of the most easily preventable of filth diseases is a disgrace to the men and methods responsible for it, and the wholesale shipment of advanced cases of typhoid fever by rail to be picked up off our streets as they drop is a species of damnable inhumanity which the medical profession of this country will neither forget nor forgive.

W. Gilman Thompson, M.D.

New York, September 6, 1898.

Therapeutic Hints.

Retropharyngeal Abscess.—Henry Koplik divides these into distinct sets of cases: (1) the acute—(*a*) pointing wholly internally, (*b*) pointing internally and externally, (*c*) forming chiefly an external tumor; (2) chronic tuberculous abscess; (3) septic abscess, resulting from an infection or accompanying the exanthemata, which burrow and burst into the mediastinal tissues or important structures in the neck and may cause death. An acute idiopathic retropharyngeal abscess is an impossibility. Stomatitis, the anginas complicating the exanthemata, affections of the structures about the tonsils and nasal cavities in grippe, may be considered as causative factors. The writer has isolated four distinct species of streptococci in the pus from these abscesses. Diagnosis is not difficult, but there may be a misleading enlargement of the lymph nodes from adenitis. Severe pressure should be avoided in the examination, as there is danger of bursting the abscess. When the incision is made from within, an assistant must be ready to depress the patient's head if necessary to prevent the entrance of pus into the trachea. Willy Meyer believes that the incision of retropharyngeal abscess from the side of the neck is greatly superior to the old method of a direct pharyngeal incision through the mouth. It allows narcosis, with its advantages, and permits antiseptic treatment, proper irrigation, and drainage. It is often possible by this operation to extract a foreign body which has been arrested behind the cricoid cartilage. The prognosis of tuberculous retropharyngeal abscess will be materially bene-

fited by the antiseptic incision. The author favors Burckhardt's incision. The patient should be in Rose's posture.—*American Medical and Surgical Bulletin*, April 4, 1898.

Enuresis in Children.—Dr. Harold Williams divides all cases of enuresis in children into two classes: (1) Those of local origin, such as malformations, etc. (2) Those of functional origin, due to seven factors: (*a*) undue excitability of spinal centres; (*b*) anæmia; (*c*) reflex irritation; (*d*) direct volition—cold, fear of the dark, wilfulness; (*e*) auto-suggestion—the child, having wet the bed, has been scolded and punished, and the habit assumes an immense and exaggerated importance to his mind; (*f*) retarded mental development; (*g*) enfeeblement of the will, which may be due to neurasthenia or hysteria.—*Boston Medical and Surgical Journal.*

New Instruments.

A BRIDLE FOR THE CONTROL OF MOUTH BREATHING.

By NORBURNE B. JENKINS, M.D.,

KNOXVILLE, TENN.

Mouth breathing is probably coexistent with fifty per cent. of the diseases affecting the larynx or pharynx, and possibly with a greater per cent. of catarrhal affections of the nose and middle ear. It plays a

Fig. 1.

more important part in diseases of the respiratory, olfactory, auditory, and gustatory organs than casually might be supposed.

It may be observed that patients afflicted with adenoids, stenoses, hypertrophied tonsils and turbinated bodies, ecchondroses, nasal polypi, and with other obstructions of the nasopharyngeal air passages, do not, during sleep, respire through the nose. In most cases a discontinuation of nasal respiration is an enforced alternative, there being present some form of obstruction. It may be due to a habit of breathing, resulting from some former temporary encroachment on the air passages of the nose and pharynx. On the other hand, such obstructions often appear as the results of the non-use of the nose in respiration.

The accompaning illustrations show a bridle, which from successful experience is offered as a corrective of the above-mentioned injurious habit.

This device is made of four strips of cotton webbing, one inch wide, and commercially known as "stay binding." It has but one fastening, which

Fig. 2.

may be a button, a safety pin, a buckle, or a knot. The bridle should be adjusted to the head of the patient by the use of pins (see the illustrations), and then removed and stitched as soon as fitted. The cost of this bridle is five cents. It can be fitted in

Fig. 3.

two minutes. The fit should be sufficiently loose for comfort. After a few nights' use it may be tightened if necessary.

The primary result of the use of this contrivance is a noticeable change in the cleanliness of the mouth on awakening. This is largely due to the absence of

the products of micro-organisms in the saliva. When lodged in the secretions of the sleeper's open mouth they find favorable conditions for speedy propagation. In high dry altitudes the results are less marked, because of the freedom of such atmospheres from all forms of bacteria.

In nasal catarrh (provided there is no sinus complication) a perceptible decrease of the secretion will speedily follow the use of the bridle.

The hypertrophied tonsil frequently resumes its normal condition, and adenoids occasionally disappear after the continuous use of this bridle for a few months.

Catarrh of the middle ear is of frequent occurrence in mouth breathers, and in many instances may be permanently relieved by the use of the bridle in connection with the customary treatment.

Morbid conditions of the pharynx and larynx are always benefited by a resumption of nasal respiration.

All such obstructions as enchondroses, polypi, deviating septa, exostoses, etc., claim the attention of the surgeon, and after his work with the knife the ordinary nasal detergents should be used for a few days prior to the wearing of the bridle. The metal dilators of Dr. Lenox Brown, in such cases as they are recommended for, will greatly facilitate the acceptance of this mechanism and the return to nose breathing.

A mild carbolized solution of cocaine injected with an atomizer into the nasal cavities before retiring will increase their calibre, and may be used with good effect by the patient while becoming used to the bridle.

As a prophylactic measure against the contraction of pneumonia, bronchitis, and other respiratory diseases, which attack the great masses who sleep in cold and damp bedrooms, enforced nasal respiration with the use of the bridle should prove valuable. No better demonstration of the injurious effects of an improper moistening and warming of the inspired air can be made than the study of exaggerated cases of hare-lip and cleft palate, which usually in early infancy contract some fatal form of respiratory disease.

The cosmetic effect of nasal respiration is not to be overlooked. In childhood the protruding jaw, the thick lip, the atrophied nose, together with other facial deformities, can in many cases be relieved or prevented by the timely use of this bridle.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 3, 1898:

	Cases.	Deaths.
Tuberculosis	98	140
Typhoid fever	181	24
Scarlet fever	55	5
Measles	38	4
Diphtheria	90	24
Chicken-pox	2	0
Cerebro-spinal meningitis	0	3
Laryngeal diphtheria (croup)	7	4

A Whiff of Tobacco, and its Unpleasant Suggestion.—We do not want to rail at tobacco, but just to draw a little moral from a whiff of smoke. Go where one will, the nose, the eyes, and even the throat and bronchial tubes are assailed by smoke, that is, by a cloud of particles, every one of which has come direct out of some one else's mouth. It is not a nice idea, but let us see what else it teaches. The fumes do but make visible what is happening all the day, whether we smoke or not. Each of the tiny particles of carbon or condensed vapor, which in their millions make up a wreath of smoke, does but indicate the track taken by a corresponding particle of expired air, which, if it can carry the visible carbon, can still more easily carry the invisible microbe. Thus a whiff of smoke entering our nostrils and penetrating our lungs does but show the course which might be taken just as easily by a swarm of microbes, and serves to demonstrate one at least of the ways in which a crowded life passed in close community with our fellows leads to mischief. The passage of a whiff of smoke from mouth to mouth does, in fact, but illustrate the mode in which the well-recognized evils of rebreathing expired air are produced. It is not the air but what the air carries with it that does the harm. What is illustrated by tobacco smoke is sometimes proved in another way. In the bright sunbeams motes are said to dance, and by careful watching one may see not only how numerous these motes are, but of what nasty stuff they are not infrequently composed. The wheezy flower seller coughing over his tray of violets, the loud-voiced hawker shouting over his barrow of strawberries, the sniffling child sneezing at the street corner, the panting person who will shake out his handkerchief in the 'bus before using it, even polite people talking to each other, are all doing things which on a dull day seem innocuous enough. Let the sun shine, however, and the telltale sunbeams soon display the showers of saliva and the crowds of dust which are thus scattered in the air and can almost be traced from mouth to mouth. This is æsthetically abominable, but in the vast majority of cases probably does no harm. Here and there, however, these particles come from people who are diseased, and carry diseases to those who are healthy. The rebreathing of expired air is certainly one cause of disease, especially to those who live in towns and in close dwellings; and how real is the risk, and how readily the passage of solid particles from man to man and from mouth to mouth is accomplished, is made manifest every time a whiff of tobacco makes us cough.—*The Hospital.*

Bergmann's Views on Aseptic Methods.—It is now about a year since Professor Seidel, chief surgeon of the Brunswick Hospital, committed suicide under sad circumstances, which gave rise to much comment in the medical world. It became known that Seidel's assistants, dissatisfied with his methods, had addressed a written complaint to the Brunswick ministry, in which they charged him with neglecting antiseptic and aseptic precautions, and especially with having caused the death of a patient by operating with an imperfectly healed furuncle on his finger. On receiving this letter the Brunswick ministry sent for Professor Seidel, informed him of the charges made by his assistants, and said that an inquiry would at once be instituted, which they hoped would entirely clear him; but in the mean time they had decided to suspend him from his functions temporarily. Professor Seidel, who, like many brilliant and hard worked surgeons, was of a nervous and excitable temperament, committed suicide the next day, leaving behind him letters in which he said that, though he was innocent, the suspension from his office was a disgrace which he could not survive, and imploring his family and friends to clear his name. This duty was undertaken by his two brothers, who submitted the case to Professor von Bergmann, of Berlin, as the president of the German Surgical Society, and published his reply, in which he vehemently defended

Professor Seidel and condemned the behavior of the assistants. Thereupon the brothers published other letters and papers bearing on the subject, and accused the assistants of having caused the death of Professor Seidel by underhand and undeserved denunciations. A lawsuit for libel followed, which after occupying several days, terminated in a verdict for the brothers of Professor Seidel, who, the court found, had acted not improperly in the defence of his interests and good name. The chief interest of the lawsuit from a medical point of view was undoubtedly the evidence of Professor von Bergmann, which he gave in favor of the late Professor Seidel and against the assistants with such vehemence that the judge intervened more than once, warning him to beware of using injurious expressions. Bergmann said it was his decided conviction that the problems of asepsis and antisepsis in surgery were as yet by no means scientifically solved, that the most distinguished surgeons were very much at variance on the subject. He quoted the memorable "glove controversy" of this year's Surgical Congress, which showed that one and the same method was considered by some authorities a decided improvement in asepsis, and by others extremely dangerous; so that it was absurd to denounce a surgeon for not observing the precautions of certain modern methods.—*British Medical Journal.*

Alcohol in Cow's Milk.—H. Weller ("Forschungen über Lebensmittel," 1897) found positive evidence of alcohol, to the extent of 0.96 per cent., in the milk from a large dairy attached to an important distillery, where the cows were fed on distillery slops, containing 5.9 per cent. of alcohol. This milk was stronger in alcohol than most beers, but in what quantities it was given was not stated. The milk examined was perfectly fresh, free from acidity, and in other respects normal, having a specific gravity of 1.0335, with total solids of 3.37 per cent., of which 3.79 was fat.

Health Reports.—The following statistics concerning small-pox, yellow fever, cholera, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending September 3, 1898:

The Atmosphere of London.—A writer in *The Daily Telegraph* says that only by degrees are the marvellous qualities of London atmosphere becoming known. No city in the world can boast such a peculiar aerial composition as that which the inhabitants of the metropolis have served to them daily and nightly without money and without price, for neither the government, county council, nor vestries have yet attempted to tax the highly nutritive air which we breathe. Most people think that our atmosphere consists of practically nothing. Quite a mistake. It is both meat and drink. A paper contributed to the "Transactions of the British Institute of Preventive Medicine" states that even in a suburb the dust particles number 20,000 per cubic centimetre in the open air and 44,000 in a quiet room, while in the city the totals per cubic centimetre were 500,000 when taken from a roof, 300,000 in a court, and about 400,000 in a room. In other words, the air of the square mile is nine hundred per cent. thicker than in the suburbs, which is in accord with the general experience that fogs are both more dense and more frequent over the centre than in the outskirts. But what is especially interesting to learn is that, although dust is the great carrier of micro-organisms, there is only one of these per 38,000,000 atoms of dust. Thus it is calculated that a man could live in the metropolis for seventy years and absorb only 25,000,000 microbes into his system from the air, or about the same number as he drinks in half a pint of unboiled milk. Of course there are other serious objections to dust, but it is something to know that there is only one microbe to many millions of motes.

BOTTINI'S OPERATION FOR ENLARGED PROSTATE, WITH REPORT OF FIVE CASES.[1]

By HENRY H. MORTON, M.D.,

LECTURER ON GENITO-URINARY DISEASES IN THE LONG ISLAND COLLEGE HOSPITAL; ATTENDING SURGEON, DEPARTMENT OF CUTANEOUS AND GENITO-URINARY DISEASES, KINGS COUNTY HOSPITAL, AND POLHEMUS MEMORIAL CLINIC.

Of all the conditions requiring surgical interference which the genito-urinary surgeon is called upon to treat, senile hypertrophy of the prostate, which either entirely or partially prevents the emptying of the bladder, is the most perplexing.

And it is perplexing for various reasons. Unlike most of the surgical procedures of to-day, in which the indications for operation are laid down with almost mathematical precision, the operations selected for the relief of the conditions due to an enlarged prostate depend more upon the individual preference or operative habit of the surgeon than upon any rules which are definitely outlined and generally accepted.

Although a number of operations are in use for the relief of this condition, the drawbacks and disadvantages attached to each one make us hesitate a long time before advising an old man with symptoms arising from an enlarged prostate to take the chances of the uncertain results and positive dangers of any of these well-known operative procedures. The danger to life of all the cutting-operations in old men is very considerable.

The simple operation of castration carries with it a mortality of seven or eight per cent., and these are selected cases which do not include the bad operative risks, such as men with pyelitis, abscess of the kidneys, high degree of arterial sclerosis, or extreme general debility and feebleness. If we include these cases in the mortality tables, the death rate runs up to seventeen or eighteen per cent.

The operations of prostatectomy are very much more fatal and are quite out of the question in the cases which appeal to us most strongly for relief—that is, in feeble old men with a high grade of cystitis and attendant uræmic absorption, and upon whom catheterization is difficult, or impossible, from the size to which the prostate has grown.

The palliative operations for drainage are looked upon more as temporary makeshifts, and are chiefly useful in alleviating the cystitis and the necessity for frequent catheterization.

In addition to the danger of shock and later on of septic absorption through the fresh-cut wound which the cutting-operations entail, we must also consider the risk of giving an anæsthetic to an old man, who is very apt to be suffering from chronic bronchitis, who may have surgical kidneys, and who is liable to die subsequently of suppression of urine or ether pneumonia.

In consequence of all these risks attendant upon the operations, it is a general rule of practice in old patients with hypertrophied prostate not to have recourse at once to operation, but simply to keep the bladder free from residual urine by means of the catheter and to treat the cystitis by bladder washing. The use of the catheter is maintained as long as it is practicable, and the general opinion held to-day is that the only indication for operation is impending or actual breakdown in catheter life—that is, when catheterization is difficult or impossible, attended with great pain or hemorrhage, or has to be performed with undue frequency.

In the operation which I desire to speak of to-night all these dangers which I have detailed are to a great extent reduced to a minimum. An anæsthetic is not required, and the danger of a fresh-cut wound, with its blood-vessels and lymphatics severed and gaping, is avoided, because the red-hot blade, as it burns its way through the tissues, chars them, and in this way seals up all the avenues of infection.

From the fact that in most cases of enlarged prostate the obstructing bar at the neck of the bladder can be removed by Bottini's operation, and also on account of the very slight danger to life which the operation entails, I believe it to be justifiable to use it in many cases in which formerly an operation would never have been considered; and we may by its use relieve many an old man who otherwise would be condemned to catheter life, with all its attendant evils and inconveniences, for the rest of his days.

Bottini's operation of burning a channel through the enlarged prostate with a galvano-cautery is by no means a new one, for it has been in use by its originator, Professor Bottini, director of the surgical clinic in Pavia, Italy, for more than twenty years.

Bottini's original operation consisted in burning with the red-hot iron the entire prostatic urethra and charring deeply into the substance of the prostate; but of late years he has abandoned this operation and now uses entirely his later instrument, which simply cuts through the obstructing bar at the neck of the bladder. Freudenberg, of Berlin, has still further modified the instrument in certain details of construction, but the principle is the same. The results of Bottini's operation in removing the obstacle to the free outflow of urine from the bladder are eminently satisfactory in some cases, and in a few other instances the operation appears to be a total failure.

I believe the reason that some cases are successful and others are not depends upon the size of the gland and the form which the obstructing part assumes as it blocks up the outlet from the bladder.

A reference to the illustrations reproduced from plates in the admirable monograph on "The Operative Treatment of Hypertrophied Prostate," by Francis Sedgwick Watson, of Boston, will make this statement more intelligible. In Fig. 1 we have a condition of affairs which is eminently adapted to Bottini's operation. Here the obstruction consists of a narrow bar at the neck of the bladder, creating a dam in front of the post-prostatic pouch. When the bar is severed by Bottini's instrument we have a complete division of the obstruction, and perfect drainage is afforded.

On referring to Fig. 2 it is manifestly evident that Bottini's operation cannot be applied to the condition here presented. The jutting out of the bulging middle lobe would render the introduction of the instrument

[1] Read before the Kings County Medical Society, May 17, 1898.

difficult, and even if it were possible to introduce it we should simply burn a groove in the projecting middle lobe. In order to make the division effective in draining the post-prostatic pouch, it would be necessary to have the groove deep enough to divide the middle lobe into two halves, like a split apple, and Bottini's instrument cannot accomplish this.

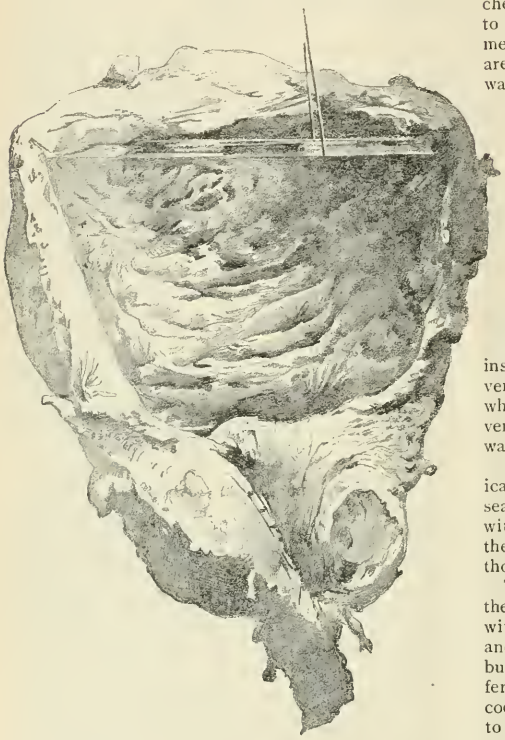

Fig. 1.

It is now pretty well accepted that the operation of castration or orchidectomy, when it does prove successful, succeeds in the cases in which the prostatic over-growth is due to a hypertrophy of its glandular elements—that is, in adenoma of the prostate, which often grows to a great size.

The growths, however, which are due to a hyperplasia of the connective-tissue stroma of the gland, and are found on rectal examination to be of moderate size and very dense, firm, and hard in consistence, do not shrivel and become atrophied after castration.

We may, then—and I offer this merely as a suggestion and not as a positive statement—divide our cases for operation into two groups:

(1) Those with dense, hard prostates, with moderate enlargement occasioned by connective-tissue hyperplasia, in which the obstruction to the urinary outflow is due to a bar at the neck of the bladder, or to the ring-like enlargement of the prostate, surrounding the urethra like a collar. Bottini's operation will relieve these conditions by dividing the obstruction.

(2) The group of cases in which the prostatic enlargement is due to an overgrowth of the glandular elements. The anatomical conformation of the growth renders Bottini's operation ineffective here, and castration or prostatectomy may succeed better in these cases.

The instrument[1] is shaped like a lithotrite, and is provided with a thin platino-iridium blade, which is concealed when the instrument is closed, but is moved backward in a slot by working a wheel at the end of the instrument (Fig. 3). This blade is heated to a dull cherry red by means of the electric current, conducted to it through a cord atttached to the end of the instrument. All parts of the instrument except the blade are prevented from being heated by a stream of cold water which constantly circulates through it.

One reason why this operation has remained for twenty years in comparative obscurity is the great difficulty of getting a battery of sufficient power to heat the cautery blade and keep it at an even heat. This difficulty has now been overcome by means of a specially constructed storage battery, which is small enough to be carried about, and yet furnishes the necessary power to keep the knife at the right temperature.

One great advantage which Bottini's operation possesses over all the other forms of operative procedure is that no general anæsthetic is required. A few drops of a four-per-cent. cocaine solution instilled into the posterior urethra is enough to prevent any very acute pain, and indeed in all the cases which I have operated upon, the patients suffered but very little pain, even while the knife was burning its way through the gland.

Before the operation is begun the presence of vesical calculus should be excluded by means of the searcher or cystoscope; not that a stone will interfere with the operation, but if a stone is in the bladder the symptoms of irritability will not be relieved, even though the obstruction is removed.

The first step in the operation consists in drawing the urine with a catheter and washing the bladder with boric-acid solution. The bladder is then emptied; and it is important that it should be empty while the burning is going on, since fluid in the bladder interferes with the proper heating of the knife. After the cocaine has been instilled and we are waiting for it to take effect, the water stream should be turned on and allowed to flow through the instrument; and during the entire time of the operation we should see that the stream flows constantly and is not interfered with by twisting or compression of the rubber tubing.

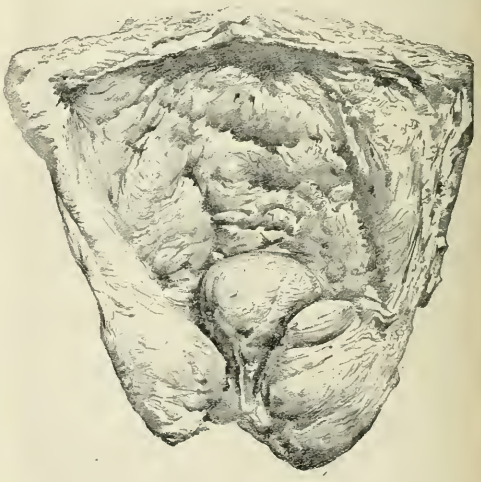

Fig. 2.

The electric current should be then turned on and the knife be brought to a cherry-red heat, and the

[1] Freudenberg's modification of Bottini's instrument and the special storage battery for it are manufactured by the Kny-Scherer Company, New York.

amount of current which is necessary to do this should be noted on the battery rheostat, as a guide for the regulation of the current after the instrument is introduced into the bladder. It is also desirable to test the blade against a piece of moist gauze. The electric current is shut off, and the operator, standing on the right side of the patient, introduces the instrument, the blades of which are closed by a "*tour de maitre*," in the same way that a lithotrite is introduced into the bladder.

Freudenberg has been in the habit of making the upper cut first, but, as the posterior cut is the most important one, I believe it better to make that one first. The instrument, with its beak pointing toward the sacrum, is hooked up firmly against the projecting lobe of the prostate, the current turned on, and a pause of ten to thirty seconds is made for the blade to become hot; then the screw is slowly turned and the thin platinum blade, which is red hot, burns its way through the projecting lobe. We know that the blade is burning its way through the tissue, because in most of the cases we are able to hear a sizzling sound by auscultating over the bladder, and the blade of the instrument is seen to be covered with charred tissue, which adheres closely to it when it is withdrawn.

FIG. 3.—Freudenberg's Modification of Bottini's Incisor.

I consider it of prime importance to make all the cuts slowly, and so that the tissues may not be merely divided but thoroughly charred on either side of the cut and to some little depth; to this end I am in the habit of leaving the current on, so that the knife may continue to retain its heat as it is screwed back, passing again through the furrow burned in the tissues and charring them once more. When the knife is again buried in its slot in the shaft of the instrument, the electric current is turned off.

The next cut which can be made is the anterior. The beak of the instrument is turned so that it points toward the pubes, and the instrument is hooked firmly against the anterior face of the prostate, which is burned through in the same way that the posterior cut is made.

A third or lateral cut may be made, or not, as the necessities of the case demand. The procedure is done in the same way, and whichever lateral lobe of the prostate, either right or left, is most hypertrophied, is burned through.

The length of the cuts will depend, of course, upon the amount of enlargement of the prostate, but in the cases I have operated on, three centimetres for the posterior cut and two centimetres for the anterior and lateral cuts respectively, seemed to answer the purpose. The time consumed was about sixty-five seconds for the three-centimetre cut, and fifty seconds for the two-centimetre cut.

The after-treatment of these cases is very simple. The patient is kept in bed for from two to four days, as there is always a feeling of depression and languor after the operation. There is also a slight rise of temperature, reaching about 100° F. for a day or two. Remedies are to be administered to keep the urine sterile, and if there is much atony of the bladder strychnine is indicated. The patient is allowed to pass urine, and the use of the catheter is undesirable unless retention of urine occurs. This is an accident which is not infrequent, and proceeds from the swelling and congestion of the mucous membrane, which result in consequence of the traumatism and may be sufficient to close up and occlude the urethral orifice.

A slight amount of bleeding, which is only enough to discolor the urine, occurs in all the cases, but in rare instances a considerable amount of hemorrhage may occur. In the cases reported in which this accident happened it was always easily controlled by tying in a large-sized rubber catheter and leaving it for twenty-four hours. If this were not sufficient it might be necessary to perform external urethrotomy and introduce a perineal drain into the bladder and pack gauze tightly around it.

In the cases reported by Freudenberg the existing cystitis began to improve at once, on account of the possibility of keeping the bladder drained and empty.

The question naturally arises whether it is not necessary to pass sounds after the operation, as would be done after an internal urethrotomy, in order to keep the cut surfaces from growing together again. Bottini and Freudenberg expressly state that the passage of sounds is not necessary, and that the outflow of urine is quite enough in itself to force apart the incisions and prevent their union.

In some cases complete division of the obstructing bar is not made and there is no relief of the retention. In such instances the operation must be repeated within a week or two. It is by no means an infrequent occurrence to fail in the first operation and be obliged to repeat it. But when the operation is successful and the patient is relieved from the obstruction, the cure is permanent. Bottini says that in all his experience he has never had a single case which relapsed.[1]

With regard to the tabulated results which have thus far be enpublished, Bottini[2] reports 80 cases operated upon, with 2 deaths. The 80 cases operated upon are divided into two groups: 57 cases were operated upon with the cauterizer, his old instrument, which charred and burned the entire prostatic urethra and which he has now abandond; of these 57 cases 43 were successful (32 cured, 11 improved); and 23 cases were operated upon with the incisor (the instrument above pictured), of which every one was successful.

Freudenberg,[3] of Berlin, has operated upon 13 cases with the following results: one patient died twenty-four days after the operation; another died as the result of the operation from embolic pneumonia. Of the 11 cases remaining 7 had complete retention of urine and had been entirely dependent upon the catheter from two months to five years. After the operation the retention was entirely relieved and the patients were able to pass urine spontaneously, and 4 of them were able to dispense entirely with the catheter; the other 3 had some residual urine and had to pass a catheter occasionally. Four other cases suffered from frequent and painful urination and spasm of the bladder, and they were all markedly benefited by the operation.

In one instance the patient had been urinating sixty

[2] Berliner klinische Wochenschrift, April 12, 1897.

[3] New York Medical Journal, February 12, 1898.

or seventy times in twenty-four hours, and after the operation the evacuations dropped to eight or ten times in the twenty-four hours.

Dr. Willy Meyer,[1] of New York, who was the first to use Bottini's instrument in this country, has operated upon five cases with one death. Two of his cases were very much benefited by the operation; one patient in particular, who had used a catheter for four years and had eight to ten ounces of residual urine, was entirely relieved by the operation. The residual urine has completely disappeared and he urinates four or five times during the day and once at night.

My own personal experience with this procedure is confined to five cases which I have operated upon by Bottini's method, and which I beg to report as follows:

Case I.—J. McC——, sixty-two years old, came into the hospital on account of frequent urination at night. Passes water from four to nine times, he says. Examination, prostate one and one-half inches in diameter, hard and dense. Residual urine, one ounce, clear. Patient childish and mentally irresponsible. February 25, 1898.—Bottini's operation. April 24th.—Present condition: Urinates four or five times in day, twice at night (as nearly as can be ascertained). Residual urine, one drachm.

Case II.—C. G——, seventy-five years old. Complains of frequent urination, four or five times at night, every hour during day. Prostate size of horse-chestnut, moderately soft. Residual urine, four ounces and contains pus. February 25, 1898.—Bottini's operation. April 20th.—Present condition: Gets up to urinate two or three times at night; four times through day. Residual urine, four drachms, still turbid.

Case III.—Charles W——, aged fifty-seven years. Has had trouble two years; urination very frequent, fifteen times at night, eight or nine times a day. Urine fetid and purulent. Prostate one and one-half inches in diameter. January 25, 1898.—Bottini's operation. Had dribbling and incontinence of urine for five days after operation, which disappeared. February 25th.—Present condition: General condition improved since operation. Can now hold his water three hours at a time.

Case IV.—J. C——, aged fifty-five years, has had trouble three or four years. Passes water three times at night and every three hours through the day. Prostate one and one-half inches in diameter, hard and dense. Residual urine varies from twelve to sixteen ounces and is clear. March 8, 1898.—Bottini's operation. Two days afterward had an attack of retention of urine and had to be catheterized. A bad attack of cystitis followed, but improved under bladder washing and salol and urotropin internally. April 26th.—Present condition: Cystitis still present but improving. Holds water two hours at night and one and one-half hours through the day. Can throw a fair-sized stream and with a good degree of force. Residual urine, one ounce.

Case V.—T. H. T——, aged sixty-six years, has been troubled fifteen years. Complains of getting up to urinate five or six times at night. Urinates every two hours through the day. Stream is not propelled with any force; wets his shoes. Prostate one and one-half inches in diameter and hard. Residual urine varies from six to ten ounces. March 8, 1898.—Bottini's operation. April 10th.—Present condition: Gets up twice at night to urinate. Urinates every two or three hours through the day. Passes thick stream with good force. Residual urine, one-half ounce. Clear and with but a slight quantity of mucus in it.

In order to place before you the facts, I would like to present a brief summary of these five cases and the results of the operations. The ages of the patients ranged from fifty-five to seventy-five years, and in each case the prostate chanced to be of the small, dense, fibrous variety. The troublesome symptom was frequency of urination by day and notably at night. The residual urine which remained in the bladder after the patient had endeavored to evacuate it completely was, taking each case separately, one ounce, four ounces, ten ounces, and sixteen ounces respectively. An examination was made in each case, to exclude the presence of stone in the bladder, stricture, or any other local abnormality.

Bottini's operation was done with the usual three cuts—the posterior, three centimetres long; lateral and anterior, two centimetres long. Cocaine was used as an anæsthetic.

The result of the operation was in every case to reduce the frequency of urination and to remove the obstruction offered by the prostate, so that the patients could entirely and completely evacuate their bladders. In each case this was demonstrated by introducing a catheter and finding only from three to eight drachms of residual urine, and the patients were able to dispense with the catheter, which they had formerly depended upon to empty their bladders.

Since the operations the urine in each case is propelled in a thick, broad stream, whereas before it was feeble and trickling, thus showing that the obstruction which formerly existed at the outlet of the bladder has been removed.

I wish only to say in conclusion that I believe Bottini's operation will in a great number of cases fill all the indications, and will take the place of the operations for prostatic hypertrophy which are now in vogue, and which are mutilating in character, unsatisfactory in their results, and attended with a high rate of mortality.

THE PHYSIOLOGY OF THE LIVER AND THE RÔLE IT PLAYS IN DIGESTION AND NUTRITION.[1]

By GEORGE E. DAVIS, M.D.,

LAWRENCEBURG, KY.

Nutrition, or the power of converting dead food material into living substance, is the foundation of physiology and all life. The term in its broadest sense may be used to embrace the processes of digestion, respiration, absorption, and excretion through which food materials are prepared for the activity of the living molecules and the waste products of activity are removed from the organism. The act of converting dead material into living protoplasm is probably a synthetic process, and may be specially designated as assimilation or as anabolism, as opposed to disassimilation or katabolism—the destruction of the complex substance of the living molecule. Assimilation and disassimilation, then, or anabolism and katabolism, acting co-ordinately, constitute an ever-recurring cycle of activity, which persists as long as the body retains its vital structure, and which is designated under the name of metabolism. If nutrition is the foundation of all life, the disturbance of this important process manifestly is the foundation for disease and destruction of life.

The composition of living substance is very complex, and a study of the vital processes involved in metabolism reveals the great instability of living matter and makes apparent how disturbances of nutrition may be the foundation or predisposing cause of all disease. The food that is eaten furnishes the material for growth and excretion. Living things can

[1] Read before the Kentucky State Medical Society at Maysville, Ky., in convention May 11, 12, and 13, 1898.

only transform matter and energy; they cannot create or destroy them. Nutrition conserves the elaboration of this material, and, since the liver is the largest gland in the body and performs the double function of secretion and excretion, it plays an important part in this transformation.

In a previous paper, in speaking of gastric peptones, I said that "these peptones are not ready for absorption into the circulation. Peptones when injected directly into the blood current behave as foreign bodies and produce a narcotic effect, not unlike that resulting from the injection of bacterial toxins." The statement was also made that, "the food stuffs having been acted upon by the ferments of the several digestive juices, the proteids are reduced to proteoses and to peptones and the carbohydrates into maltose. Absorption occurs principally in the small intestines. Now since, as above stated, peptones and maltose cannot be absorbed as such into the circulation without deleterious effects, the conclusion is inevitable that during the process of absorption they must undergo some further transformation which adapts them for the direct nutritional needs of the body." It was further stated that "there are two theories as to the nature of this transformation. One is that the epithelial cells of the intestinal mucosa possess a ferment—invertin—which is capable of further transforming peptones into simple products, as serum albumin, globulin, etc. And it is also claimed that these cells possess another ferment which further reduces maltose into glycogen. The second theory supposes that the leucocytes of the adenoid tissue surrounding the intestines have the functional activity of absorbing and transforming peptones into cell protoplasm, which thus gains entrance into the circulation through the mesenteric glands and thoracic duct.

Since writing the paper quoted from above, citing the theories of the nutritive processes as related to the transformation of the food stuff as absorbed from the intestines, I have changed my opinion materially. While it has been shown that the intestinal secretion contains an amylolytic enzyme which aids in converting starches into maltose, it has been also fairly well demonstrated that it has no specific action on proteids and fats, that it contains neither a proteolytic nor a fat-splitting enzyme. This transformation occurs principally, I believe, in the liver as the result of the metabolism occasioned through the agency of the protoplasmic material of the liver cell, which is the anatomical and physiological unit of the organ.

The liver through its manifold functions plays an important part in the general nutrition of the body. Broadly speaking, the liver has two great functions: 1. On the one hand, it transforms the materials of assimilation absorbed from the intestines, converting the sugars into glycogen, the peptones into serum-albumin and globulin, etc. These last products represent the simplest and most perfected development of these substances for assimilation and nutrition of the cells of the various tissues of the body. 2. On the other hand, the liver transforms the materials of disassimilation, and completes the development of these substances from non-diffusible colloids into crystalloid dialyzable material before they pass into the excretory passages. Urea, for instance, is thus formed, which is given back to the blood to be eliminated by the kidneys. And since urea is a strong physiological diuretic, the liver indirectly aids elimination of other waste products of the tissues by furnishing a powerful stimulant to the most important excretory organ of the body, viz., the kidney. The biliary function of the liver also represents the transformation of waste products of metabolism and furnishes an example of direct elimination of an enormous amount of poisonous material, contained principally in the coloring matter and the biliary acids. When the bile is poured into the intestines the coloring matter and biliary acids are precipitated and rendered innocuous or non-absorbable. The biliary function of the liver further conserves the nutritional interests of the body by emulsifying fats, which process renders them absorbable by the lacteals, which convey them through the thoracic duct to the general circulation to furnish nutrition and potential energy for the kinetic functions of the organism. The fats, then, are the only food products that are not absorbed by the capillaries of the intestines and carried to the liver for further elaboration before reaching the general circulation. This metamorphosis needs must occur, therefore, during the process of absorption by some act of the cells of the intestines, else the transformation must occur after absorption through the agency of the leucocytes. The latter theory is the more probable.

A brief review of these three great hepatic functions will easily demonstrate that the physiology of the liver not only plays an important rôle in digestion, assimilation, and nutrition; but, since it is the portal or gateway, with one exception, through which all food stuffs, or other materials whatever, for that matter, whether they be elements of life or death, enter the general circulation or vital domain of the organism, it has another function, in that it acts as a sentinel, discriminating between the good and the evil, selecting the good and rejecting the bad. The liver, therefore, in the great laws of digestion, nutrition, and life, represents the cardinal principles of affirmation and negation of the commandments and says, "Thou shalt" and "Thou shalt not," and will not hold him guiltless who is so temerous as to abuse or transgress those laws.

Our further study of the liver under the above divisions will deal first with the metabolic changes produced by the liver cell on the soluble products as absorbed from the alimentary canal, such as proteids and sugars; second, we shall treat of the formation and physiological significance of the bile.

In studying the changes the proteid food stuffs undergo during gastric and intestinal digestion, we learn that the proteoses and peptones thus produced are not ready for assimilation into the general circulation, but are further transformed by the metabolic activity of the intestinal cells into simpler albumins and into waste products, such as ammonia compounds, respectively; and these in their turn are conveyed by the portal vein, along with the products contained in the blood from the spleen, to the liver, there to be submitted to the metabolic activity of the liver cell, which converts the albumins into still simpler albumins, and the ammonia compounds and other end products of nitrogen disassimilation and oxidation into urea. The liver cells elaborate proteids into very simple forms, which then are carried through the general circulation to the cells of the various tissues, there to reach their final and ultimate metamorphosis into combined proteids by the metabolism of these cells, which convert them into living protoplasm to supply their nutrition, growth, life, and potential energy; their oxidation results in final waste products, which are sent to the liver to be converted into urea, and this again is returned to the blood to be eliminated by the kidneys. It has also been shown that the liver can produce glycogen from proteid food. This is a point worthy to remember, for, as glycogen is a carbohydrate and contains no nitrogen, it implies that the proteid molecule is dissociated into a nitrogenous and a non-nitrogenous part, the latter being converted into glycogen by the liver cells.

In dealing with the carbohydrates which are absorbed in the form of sugar and dextrose, we touch

upon one of the most important functions of the liver —the formation of glycogen. The starches are converted in the intestines into maltose, and during the process of absorption this is transformed by the epithelial cells into dextrose; this is carried by the portal vein to the liver cells, which by their metabolic action convert a part of it into glycogen, which is stored in the cells as a reserve supply that is volunteered to the service of the body cells when they require nutrition. The liver by storing glycogen acts as a commissary. The dextrose not converted into glycogen by the liver enters the general circulation, and the excess not required for immediate use of the tissues is temporarily converted into glycogen in the muscles and is stored there, to be again changed to dextrose before being used. Like starch, other carbohydrates, as cane sugar, milk sugar, etc., are absorbed as dextrose, and are similarly elaborated during assimilation and nutrition.

An analysis of the biliary function of the liver from a physiological standpoint shows the bile to be partly an excretion, carrying off waste products of metabolism, and partly a digestive secretion, in that it plays an important rôle in the processes of absorption generally, but especially in the emulsification and absorption of fats. The chief constituents of the bile, in addition to water and salts, are the bile pigments, bile acids, cholesterin, lecithin, etc. The bile pigments originate from hæmoglobin, resulting from the destruction of the red blood cells in the spleen. Cholesterin probably represents the waste products of cell life and is held in solution by the bile acids. Lecithin represents chiefly the disassimilation of nerve tissue. The bile acids are elaborated by the action of the liver cells and probably represent the most important ingredients of the bile.

The general physiological importance of the bile, then, is as an excretion, in that it removes from the body waste products of metabolism and is important as a digestive secretion in the part that it takes in the absorption and digestion of fats.

The above brief review of the physiology of the liver fairly demonstrates the claim I make, that the liver is the most important digestive organ of the body. To begin with, through its biliary function it prepares fats for absorption and digestion. And again, while the stomach, pancreas, and intestines perform the primary digestion of proteids and carbohydrates, the liver performs the secondary digestion and elaboration of these materials; truly a more important function, for it has been shown by many reliable investigations and numerous experiments that the normal products of primary digestion act as toxins or foreign bodies when introduced directly into the general circulation. This leads us to reflect that the welfare of the body invokes the good offices of the liver in the performance of the important function of rendering sentinel service, protecting the system not only from auto-intoxication that would result from direct absorption of these primary products of digestion, but also from poisons that may have been introduced as such with the food, and from alkaloids or toxins that may have resulted from fermentation and decomposition of the foods and absorbed along with the said products of primary digestion. An analysis of the blood in the portal vein and hepatic veins shows that the blood in the former is twice as toxic. More evidence of the protective powers of the liver to the body from toxins and waste products of metabolism is furnished by an analysis of the bile. The toxic principles of the bile reside in the bile pigments and bile acids, which are rendered inert on reaching the bowel by being precipitated by the acid chyme. Precipitation renders them non-absorbable and they are eliminated by the bowel. The bile is about nine times as toxic as the urine, which furnishes an adequate idea of the importance and amount of direct elimination of poisons by the liver. If a stronger case is wanted to prove the importance of the liver as an organ concerned in digestion and nutrition, what better evidence could be wished than the great waste and rapid decline witnessed in malignant jaundice and acute yellow atrophy of the liver?

It can be readily understood, therefore, how even temporary disturbances of primary digestion may pervert the functions of the liver in its secondary digestion and elimination of waste products, in consequence of which acute pathological conditions manifest themselves. When the digestion—primary and secondary—of proteids is interfered with, imperfect albumins reach the circulation, which, though not having been properly transformed for elimination, nevertheless are forced through the kidneys and escape in the urine. Their elimination is a source of irritation, inflammation, and pathological change in the kidneys. Again, under the above circumstances the end products of proteid metabolism in the tissues are imperfectly oxidized, and when brought to the liver to be prepared for elimination, on account of the perverted hepatic functions, instead of being converted completely into urea, they reach only a retrograde metamorphosis, such as uric acid and the xanthin compounds, which, if retained in the system, poison it; and when forced through the kidneys, which are not constructed for their elimination, irritate and disease them. However, the origin of uric acid, though it represents the end products of the metabolism of the proteids, has not been definitely settled. It has been suggested that it represents the waste products in the metabolism of leucocytes in the spleen. In response to a late personal inquiry of Stewart, of Philadelphia, he informs me that he is inclined to the latter theory, and says: "I should tell you that all the evidence is most decidedly against this product being formed in the liver. Only in certain conditions is uric acid formed this side of the kidneys, and then it is most likely produced in the spleen, as in leukæmia. It seems somewhat curious, but there are data supporting this also, that uric acid is sometimes formed from urea by the kidneys instead of the reverse being the case. This is by the union of urea with a substance termed glycocin. A great deal that is attributed to uric acid is really not due to it at all, but to toxins of various undiscovered source. I think it little doubtful that other xanthin bodies than uric acid are the causes of that which is attributed to uric acid itself." But since uric acid is formed in the liver of birds and reptiles instead of urea, and represents the ultimate products of proteid metabolism in those animals, reasoning from analogy, it is suggested that the liver may be the source of uric acid and other nitrogenous substances, as xanthin, hypoxanthin, etc., which are closely related to uric acid, and all of which represent the disassimilation of proteids.

When the digestion and assimilation of the carbohydrates are disturbed, the glycogenic function of the liver is marred. Sugar reaches the circulation in imperfect forms and undue amounts, and, while being eliminated, inflames and diseases the kidneys.

Disturbances of nutrition, then, explain the origin of many illnesses of an acute character, and, in my opinion, rule the largest number of chronic diseases. When we enter the domain of diathesis and diathetic diseases—the most chronic of all pathological conditions—we can reasonably incriminate no other cause than disturbances of nutrition. To disengage diatheses from the mystic cloud which surrounds them and render them physiologically intelligible, they must be regarded "as a permanent disturbance of nu-

trition, which prepares, provokes, and maintains different diseases, as seen in their location, their evolution, and pathological process."

The arthritic and scrofulous diatheses are permanent nutritive disorders, which once acquired may become hereditarily transmissible.

The daily round of human life is a repetition of integration and disintegration, of processes of building up and breaking down. The breaking down is caused by perverted nutrition, which leads up to disease and dissolution by improperly preparing the material introduced for building up, and by failing to convert the toxic waste products into suitable forms for ready elimination, which are retained and act as poisons. Perverted nutrition may be responsible even for the development of new substances which may become toxic. "Thus the organism in the normal as in the pathological state is a receptacle and laboratory of poisons. Bouchard in his 'Auto-intoxication' clearly indicates to us that man is constantly standing, as it were, on the brink of a precipice. He is continually on the threshold of disease; every moment of his life he runs a risk of being overpowered by poison generated within his system. Self-poisoning is prevented only by the activity of the excretory organs, chiefly the kidneys, and by the watchfulness of the liver, which acts the part of a sentinel to the materials brought to it by the portal vein from the alimentary canal."

The liver is a great physiological protector and preserver of the organism in three ways: 1. It prevents disease. It constitutes a barrier not only against poisons introduced with the foods, but against substances which result from perversion of the primary digestive processes in the alimentary canal, such as alkaloids of fermentation and putrefaction. 2. The liver combats and controls disease by perfecting the ultimate steps of digestion, thus furnishing nutrition and munition to the army of cells in their battle with microbes and toxins. 3. The liver preserves the health and hygiene of the body by directly eliminating toxins and waste products of metabolism through the bile into the intestines, and indirectly by furnishing the most powerful physiological diuretic, urea, to stimulate the most important excretory organ, the kidney, thus aiding the complete elimination of the waste products of normal disassimilation, as well as the refuse resulting from the carnage in the combat of the cells against disease.

May 10, 1898.

POTT'S FRACTURE.[1]

By R. W. KNOX, A.M., M.D.,

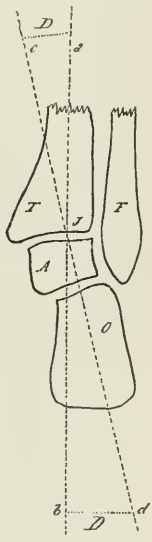
HOUSTON, TEX.

THE true nature of this injury was described for the first time by Sir Percival Pott in an article on "Fractures and Dislocations," in the year 1768. The same anatomical drawing used by this early writer and operator is still copied by modern works on surgery, and his classic description stands unchallenged in its accuracy after the lapse of more than a century. In an accident that is so common and at the same time fraught with so much danger to the usefulness of the limb, and possibly the life of the patient, we should have exact ideas of its nature and the method of treatment best adapted to secure the best results.

There seems to be no doubt of the fact that even with good care and attention some cases will result badly, and a malpractice suit may reward a faithful effort, yet it is my opinion that the more general adoption of a line of treatment to be proposed, and one that is by no means new or novel, will result in securing more serviceable limbs.

The ankle has the "ginglymus" variety of joint with its two motions, flexion downward and backward, and extension upward and forward. The slight lateral motion, which is principally inward, takes place at the subastragaloid joint. The maleoli of the tibia and fibula respectively overlap the sides of the joint, and with their strong ligamentous attachments make the joint a very secure one, and at the same time prevent a lateral motion. The convex surface of the astragalus fits a corresponding concavity in the articular surface of the tibia and gives the joint a rocker-like motion in the two directions named. The internal condyle is shorter than the external, but is compensated for in length by the deltoid ligament, which is unusually strong, especially in its attachments to the condyle. This ligament when subjected to a great strain, as in Pott's fracture, often escapes rupture by carrying away a part of the internal malleolus, to which it is attached. The external lateral ligament protects the external condyle, assisted by the anterior, posterior, and interosseous ligaments.

The injury known as Pott's fracture is a dislocation as well as a fracture. The fibula is fractured from one and one-half to three inches above the tip of the external malleolus, while the astragalus is dislocated from the tibia in an outward direction consequent upon the rupture of the deltoid ligament, or, what is more frequent, a portion of the internal malleolus, to which the deltoid is attached. The twisting-force which the foot is supposed to exert at the time of the accident is due to the action of the peroneal muscles after the foot has been dislocated, for we notice that it immediately resumes its original distortion if the reduction is not enforced with the proper supports. The tilting of the astragalus outward fractures the fibula, and, the force continuing, ruptures the internal lateral ligament. In rare cases the force is sufficient to make the dislocation a compound one, the articular end of the tibia being forced through the connective tissue and skin after breaking away from its ligamentous connections. That an outward dislocation of the foot should be so much more common than the opposite condition is easily explained. The long axis of the leg does not pass through the centre of the supporting surface of the heel, but near its inner border. A force transmitted through the long axis of the leg would therefore find its point of least resistance at or about the tibio-fibular articulation, for at this point the long axis of the leg makes an angle with the conjugate diameter of the tarsus. In other words, there is a natural outward displacement of the foot beginning at the ankle, and no matter how direct the force transmitted through the leg, a dislocation of the astragalus from the tibia and a fracture of the fibula is the most probable result (see cut). Dr. Wight, of the Long Island College Hospital, states that he has treated a dislocation of the foot complicated with Pott's fracture, in which the sole cause was the normal curve at the ankle-joint. In this case a heavy weight fell upon a man's knee when the foot rested upon the ground and the leg was perpendicular to the foot. The force in this case must have been very great. The appearance of the



[1] Read at a meeting of the South Texas Medical Association, June 29, 1898.

foot after such a fracture is especially characteristic. The foot is displaced outwardly, the toes turn out, and the external border of the foot is inclined to turn slightly upward, while the internal border is correspondingly depressed. The internal malleolus is very prominent and presents a sharp ridge if the ligament has severed a part of the condyle. An angle is noticed on the external side at the position of the fibular fracture. The foot is freely movable and reduction is not difficult unless interfered with by detached pieces of bone or ligament coming between the opposing surfaces. Hamilton, in his work on fractures, mentions a case in which he found it impossible to reduce the dislocation, the difficulty being caused, he thought, by the interposition of a fragment of the tibia which had been detached by the interosseous ligament and had become displaced in the joint. It is my opinion that these displaced fragments are largely responsible for faulty union and constant pain seen in some cases. When such a condition of affairs is suspected, an opening of the joint for the removal of fragments and correction of displacement would be admissible. This has been done very successfully as a secondary operation in cases of faulty union when locomotion was impaired.

Dr. George F. Shrady reports such an operation. His patient weighed over two hundred pounds. The dislocation was outward and backward; the inner malleolus was fractured transversely and displaced downward and forward with the tibia fractured in the usual place. For two years the foot was practically useless on account of pain in attempting to walk. A resection was made of the articular surface of the tibia and the ununited fragment of the fibula. The bones were sawn through *in situ* with the subcutaneous saw; the astragalus was not disturbed. The tendo Achillis was divided. The sawn surface of the tibia was brought in contact with the articular surface of the astragalus, a drainage tube was put in, and the limb was enveloped in plaster. A good result with a useful limb is reported.

Treatment.—With the exception mentioned, reduction is easy, the difficulty being to prevent a constantly recurring tendency to displacement of the foot outward and backward. This is accounted for by the action of the peroneal muscles and tendo Achillis. In order to prevent this the parts must be restored to the original situation, and kept so by a firmly fixed dressing until ligamentous union is accomplished. Absolute coaptation with a fixed dressing that is not too often disturbed and is worn for a long time is the *sine qua non* for a successful result. Mansell Moullin states that if the distance between the malleoli is increased but slightly lameness and serious disability are sure to follow. If the line of union is not perfect in every respect, an imperfect action may be expected. No other joint is subjected to more pressure by weight and muscular strain, and we wonder, in fact, as we view it from all points, if so much work was originally intended for this joint, and whether it is not possible that man at one time went on all fours, in company with his simian relatives. However this may be, as regards the treatment of the injury in question there is not much difference of opinion. In Dennis' recent work on surgery the writer of the article on fractures states that the only two dressings worthy of mention are the plaster of Paris and the splint of Dupuytren. The latter is not much used at the present time, as it is more difficult to apply accurately and confines the patient to one position in bed. The plaster is by far the best and most comfortable of all dressings for fractures about the leg and ankle-joint. The most important point in connection with this dressing is the manner and time of its application. In order to get good results the leg should be put up at once, if possible, and not after an interval of one day or one week. Such delay cannot always be avoided, although I believe it to be absolutely prejudicial to the future usefulness of the limb. In this connection I might state that this rule applies with the same force in all other fractures; not only do early coaptation and fixation insure better union, but they also relieve the patient of much unnecessary pain. In fact it has become an established rule in surgery that reduction should be effected at the earliest possible moment, otherwise the swelling may increase the difficulty, while the muscles become shorter, harder, and more intractable. A fractured bone until properly set is a constant source of irritation to the surrounding tissues.

It is no special contraindication to the use of plaster that the parts should be swollen when it is applied, for if swelling has already taken place the plaster will reduce it; and if no swelling has occurred it is not likely to do so after the dressing is in place. An exception to this rule might be taken if the parts were much bruised, or in case of old age or of much impairment of the patient's constitution. The plaster should be put on evenly and firmly over good wadding, and there is rarely an indication for its removal until the swelling subsides or the limb is reduced in size on account of enforced inaction. In cases in which it is decided to put on the plaster when swelling is present, and the constitution of the patient is such that an undue swelling is to be apprehended, I am in the habit of cutting the plaster down in front before it is thoroughly dry and applying a roller bandage. This is especially advisable when the patient cannot be kept under strict observation for the first twenty-four hours.

My first case of Pott's fracture was a partnership one and occurred in the early days of my professional career. The patient was a stockman and the accident happened in some way while a steer was being roped from the ground. When the case was first seen there was a little swelling, and the ancient fracture box was called into requisition; and after this a tin splint, approximating as nearly as possible to a fit, was applied. The result in this case was not satisfactory to the patient, but was of great benefit to myself. My next cases were treated with an immediate plaster dressing, and the results have been much better.

I was recently called in consultation with Dr. W. B. Olive, of this city, to see a most interesting case of compound Pott's fracture. The patient, A. M——, while riding in an electric car, and fearing a collision from another car, jumped to the ground, alighted on his right foot, and produced the following injury: The foot was turned out almost to a right angle with the axis of the leg, and the tibia, divested of its ligamentous attachments, was protruding through the skin for the distance of one and one-half inches. The interosseous ligament had detached a portion of the external articular end of the tibia, the direction of the fracture being upward and outward, and the fragment separated was about one inch in length. The deltoid ligament had detached a portion of the inner malleolus. This fragment was firmly fixed to the ligament and was lying within the joint cavity. Before reduction was effected the entire limb was rendered aseptic, the wound was enlarged, and the cavity of the joint was thoroughly irrigated with a 1–5,000 bichloride-of-mercury solution. The fragments of bone were removed, with the exception of the one detached by the interosseous ligament, and firmly held in place by the side of the fibula. Before the joint was closed another irrigation was made with the bichloride, followed by one of decinormal salt solution. No drainage was used, for the following reasons: The joint was well cleansed and there was no hemorrhage; the

drainage tube through the joint would necessarily interfere with immediate union and might be a means of causing suppuration; it would also necessitate the early removal of the plaster with a disturbance of the joint. Furthermore, when the bones are in apposition there is no cavity for the accumulation of blood or serum, and what fluid of this kind that might be thrown out would find ready exit between the interrupted sutures as the points of least resistance. The drainage is also assisted by the capillary action of the absorbent cotton surrounding the limb. In this case a smooth, rather thick wadding of carbolated cotton was used, and proved sufficient to absorb all the serum and blood thrown out. No swelling occurred and the patient complained of no pain. After a few days a window was cut in the plaster over the seat of the wound, which was found in good condition, and the stitches were removed. The original plaster was allowed to remain on for three and one-half weeks, when it was removed and slight movement was made at the ankle-joint. The limb was then encased in a liquid-glass dressing and allowed to remain for two weeks. A dressing that could be removed daily and allowed massage of the leg and motion at the ankle was now applied. The patient's leg now, seven weeks after the injury, bids fair to be a useful member.

The question as to the treatment of a compound dislocation of the ankle is perhaps still an open one. In the days of Galen and Hippocrates it was thought that death was certain if the dislocated bone was reduced, and if by any chance the bone became reduced it was immediately dislocated again. In later years and before the days of antiseptic surgery amputation was the rule in all cases. An improvement was made on this method by surgeons who have written within the past two decades, by the proposal of resection before reduction. This method was open to the objection that ankylosis was almost certain, and the injured limb was shortened from three-quarters to one and one-half inches.

The consensus of opinion at the present day is decidedly in favor of saving the foot in all cases in which the damage to the soft parts is not too great and the main arteries of the limb are intact. Reduction with resection is indicated in feeble or aged subjects. In strong and vigorous patients simple reduction of the bones, if managed according to the rules of modern surgery, will usually give good results.

In the summing up of the subject of treatment it is seen that (1) plaster of Paris is the best dressing for fractures about the ankle; (2) this dressing should be put on immediately or as soon as possible after the receipt of the injury; (3) swelling is not a contraindication to the use of plaster; (4) it takes longer for ligamentous than for bony union, and a patient should not use his foot for locomotion for several months after the injury; (5) no other dressing so nearly prevents motion, and on this account it is especially valuable in compound luxations; (6) small capillary drains may be used, but rubber drainage tubes through the joint are unnecessary and capable of doing much harm.

In Operating wear sterilized white thread gloves, cover the mouths of operator and assistants with gauze bandages, and avoid conversation during the operation. To assure sterilization of dressings, place within the sterilizer a slip of paper upon which the word "sterilized" is printed. Cause the printed word to disappear, by making the paper blue with a solution of iodine. When a temperature sufficient for complete sterilization is reached, the iodine is driven off and the word "sterilized" reappears.—Mikulicz.

VAGINAL EXAMINATIONS AND VAGINAL DOUCHES IN NORMAL LABOR.

By GEORGE P. SHEARS, M.D.,
NEW YORK,
FORMERLY HOUSE SURGEON, CITY AND MATERNITY HOSPITALS.

The subject of puerperal sepsis will not down. It is still a prominent feature in medical journals and in the discussions of societies. A recent meeting of the obstetrical section of the New York Academy of Medicine served to emphasize the fact that men of eminence and experience disagree as to the curative treatment of this condition. This being the case, it behooves us to look with especial care to the prophylactic treatment.

Viewed in historic perspective, the obstetric history of the century may be divided into three periods: the first may be called the pre-antiseptic period; the second, commencing with the long-neglected reforms of Semmelweiss, the antiseptic period; and the third, or the present one, the period of asepsis.

A brief survey of recent progress in the bacteriology of obstetrics will suffice to show what might have been expected at the outset, namely, that in normal cases we cannot improve upon the methods of nature. It has been clearly shown that the vaginal secretions have bactericidal properties, and that in normal cases antiseptic douches can only aid in causing infection.

While the discovery of the bacterial origin of puerperal infection was of incalculable importance, and the name of Semmelweiss deserves to be placed in the catalogue of the world's greatest benefactors, there is no doubt that the zeal for reform has often been carried too far, as in the preliminary douching and vaginal scrubbing in normal cases, and the routine use of daily post-partum douches, which, in hospital cases especially, have done a great deal of harm. Since, however, the non-pathogenic character of the organisms normally found in the vagina has been demonstrated, these measures have been very generally abandoned, and in normal cases we have as obstacles to perfect asepsis only frequent vaginal examinations, still often practised, and the post-partum douches, still used by many practitioners and in many hospitals. To what extent can we dispense with these?

First we note that in normal labor no douches of any kind are necessary. But what is normal labor? One thing is usually omitted in its definition, namely, that labor complicated by vaginal examinations and douches is not normal. How beautifully has nature provided against infection! Not only are the vaginal secretions antagonistic to the germs of infection, as Doederlein and others have shown, but after rupture of the membranes the cervico-vaginal canal is flooded with liquor amnii, which some one has not inaptly called a normal salt solution, and the fœtus during its emergence is at all times closely embraced by the retracting ostium vaginæ, so that neither air nor foreign body can enter. Here there is clearly no indication for a post-partum douche, unless, indeed, some enterprising person has given an ante-partum douche. In this normal physiological process nature's work is truly conservative; and here, if anywhere, the physician should be "*naturæ minister et interpres.*" The dictates of common sense, as well as the facts of comparative physiology and pathology, lead inevitably to this conclusion.

In discussing the subject of douches we are obliged to take up that of vaginal examinations as well, since in most cases the latter furnish whatever of justification there is for the former. These topics may seem commonplace. In the present period of operative obstetrics and gynæcology we are prone to forget those things that form part of the ordinary work of the practitioner, and to think that the last word has been said

about so prosaic a subject as the management of normal labor; but there is more harm done by carelessness in this department than can be atoned for by all our operative work, commendable as much of it is.

A very large proportion of the cases seen by the general practitioner are cases of normal labor in multiparæ, and would get along perfectly well without any active interference whatever. Many of them when first seen are so far advanced in the second stage as to have passed the time for most complications, and it is certainly deplorable that cases of this kind should become septic through unnecessary manipulations.

Since sepsis comes from without, and chiefly through vaginal examination, the question naturally arises: Why take the chances of introducing sepsis at all? It would of course be a dangerous absurdity to endeavor to prohibit vaginal examination in labor, but that it is vastly overdone there can be no possible doubt. It is difficult to understand why more stress is not laid upon the admitted importance of external palpation. In the study of diseases of the heart and lungs, the extremest minutiæ of physical diagnosis are carefully followed out, although in many cases the matter is chiefly of academic interest and has little if any bearing upon treatment; while in others it is so obscure that men of ability and experience differ after careful examination. In advanced pregnancy and in labor, however, we have conditions which can hardly fail to be recognized by any physician who will carefully study his cases as he meets them, and the recognition of which is fraught with vast importance.

Vaginal examination in labor is not only often unnecessary but is in itself a positive evil, and should be employed only to avoid a greater evil. Not uncommonly by the pain and nervous shock which it occasions it arrests, or unfavorably modifies, the course of labor, and it is the most common cause of sepsis.

But it may be said that with proper precautions vaginal examination is harmless. This statement is to be regarded with judicious scepticism. The same thing might be and indeed has been said about intrauterine manipulation, and theoretically it is correct, but in practice there are so many sources of error that the conclusion is untenable. Even in hospitals the lesser degrees and the ultimate consequences of puerperal sepsis not infrequently pass unrecognized.

The fact that surgeons of experience disagree as to the best method of hand disinfection confirms the conclusion of modern bacteriologists that no method is infallible.

Again, it may be said that unless frequent vaginal examinations are made complications will be overlooked. It would be easy, if time and space permitted, to take up the different abnormalities seriatim, and to show in each instance that such a statement is incorrect, at least in the case of one who has had a sufficient practical training and who uses modern methods of investigation.

When a delayed first stage threatens the life of mother or child, it is necessary to introduce the hand into the uterus for the purpose of making an exact diagnosis, if the diagnosis can be made in no other way. But who would advise this as a routine practice? The day is not distant when it will be generally acknowledged that it is no less an absurdity to make frequent vaginal examinations in normal cases, especially when the finger is passed through and around the partially dilated cervix, in order to determine the progress of labor.

In a large proportion of the cases in which external palpation fails to give satisfactory results, all necessary information can be obtained by rectal examination, as has been shown by Zweifel, Beckman, Kroenig, and others.

Every thinking man, no matter how much he may be influenced by tradition and custom, must admit that the vast majority of vaginal examinations in labor are unnecessary. Every practitioner knows by experience that unless he responds promptly when called to attend a multipara he is likely to be too late, and yet in many cases if the atendant arrives in time he makes one or more such examinations, if only as a matter of form.

A common cause of unduly frequent vaginal examinations is the inexperience or indecision of the practitioner. We often find that those who criticise the use of the forceps and the performance of obstetric operations do not hesitate to incur the grave responsibility of making frequent examinations, both before and after delivery.

The term meddlesome midwifery should not be applied to obstetric operations, which, when indicated, are really conservative measures, but rather to unwarranted interference with normal labor, and especially to examinations and douches that are not necessary. It is as futile to interfere with nature's processes of repair in normal labor as to rely upon her unaided efforts in abnormal labor.

While unnecessary examinations are objectionable before delivery, they are doubly so afterward, when a multitude of small lacerations and abrasions, which soon heal if left alone, offer as many avenues for the introduction of sepsis. Gynæcologists are fast reaching the conclusion that moderate cervical tears not causing hemorrhage are best left alone. Perineal lacerations which endanger the integrity of the pelvic floor of course require immediate repair, and the same statement applies to the larger superficial lacerations of the perineum. These, however, are not parts of normal labor, and should occur only in a limited proportion of cases. To distend the cervico-vaginal canal in search of small tears whose edges are in apposition and have no tendency to separate would be ludicrous if it were not so dangerous. It is true that an extensive laceration of the vagina, requiring immediate attention, may coexist with an apparently normal condition of the external parts; but it is the testimony of experienced obstetricians that a sufficient inspection of the vagina may be obtained by everting the posterior vaginal wall through the rectum.

The fear of post-partum hemorrhage and retained placenta, accidents which under proper management are of the rarest occurrence, leads to much intravaginal manipulation and consequent sepsis. In no condition does the "*nimia diligentia* of the tyro," as Leishman calls it, do more harm than in the third stage of labor.

The introduction of the hand into the uterus is sometimes rendered necessary by post-partum hemorrhage and other morbid conditions. Here it is of course warrantable to incur a lesser danger in order to avoid a greater one, but the occurrence of sepsis after the introduction of the hand into the uterus has been noticed by many careful observers, and this procedure should be avoided unless imperatively indicated. The practice of introducing the hand into the uterus to remove fragments of membrane which may have been torn off during the delivery of the placenta should be unhesitatingly condemned as far more dangerous than allowing them to remain. In aseptic cases they are usually passed without trouble in a few days.

We must, however, admit that in general practice many cases require vaginal examination for one reason or another. The physician's time is limited and he cannot watch his cases from beginning to end, as can the resident staff of a maternity hospital. Rectal examination, while it often answers the purpose admirably, makes a careful subsequent disinfection of the

hands necessary, and perhaps requires the presence of an assistant who can make vaginal or uterine examinations, should they be required by the occurrence of hemorrhage, laceration, or other complications.

If, then, vaginal examination is to be allowed at all, to what extent should it be limited? A glimpse at the various text-books supposed to represent modern obstetric teaching will reveal a remarkable difference of opinion. In discussing the management of labor, in the "American Text-Book of Obstetrics," Professor Jewett says: "If the physician has satisfied himself of the absence of complications, vaginal examination rarely needs repeating until after rupture of the membranes." And again: "There is seldom occasion in normal conditions for more than one or two internal examinations at the most during the expulsive stage."

In striking contrast with this are the directions found in various recent treatises and manuals, in one of which, for example, we find the statement that after complete dilatation of the os "vaginal examinations should be made every ten or fifteen minutes."

The question is not a simple one, and the answer will vary with the skill of the physician and with the circumstances of the individual case. There can be no doubt, however, that the necessity for vaginal examination diminishes with increasing experience.

Admitting that definite rules can hardly be laid down, there are yet certain general principles which may be of assistance.

The importance of an examination at some time during the last few weeks of pregnancy cannot be overestimated. Its prophylactic value is often far greater than that of examination during labor, and its general neglect is one of the most serious defects of modern obstetric practice. If pelvic deformity or other complication is suspected, careful vaginal examination will be necessary, but in the majority of cases an external examination will be sufficient. In addition to this it will in most cases be advisable to make a careful vaginal examination in the early part of the first stage of labor. More solicitude is naturally felt in the case of a primipara than in that of a woman who has already borne a child at term and who has no history of difficult labor. According to the statistics of Matthews Duncan, the liability to complications diminishes progressively after a first normal labor until the ninth.

As the head advances, the difficulty of examination becomes less, but in normal cases it can hardly be said that the necessity for examination becomes greater. There is, of course, no doubt that the ability to recognize promptly a delayed first stage and the cause of delay is of the highest importance, and in doubtful cases the accoucheur should not allow timidity or the fear of frequent examinations to prevent him from clearing up all doubt by thorough and careful investigation, under ether if necessary. On the other hand, however, he should carefully avoid falling into habits of indolent routine, and should perfect himself in every extravaginal method of diagnosis which may save his patients from examinations and manipulations that are not only unnecessary but at times dangerous.

An excellent description of the proper method of following the progress of the head by external palpation may be found in the recent work of Dr. Edward P. Davis.[1] Says this author: "Symptoms of delay or exhaustion during labor can be more readily appreciated by palpation than by any other method."

It is undoubtedly true, as remarked by Lusk, quoting Ahlfeld,[2] that under certain conditions face presentation is favored by rapid escape of the amniotic fluid, and, as prolapse of the cord and other accidents occasionally occur at this time, there is perhaps some reason for making a vaginal examination immediately after rupture of the membranes. This will also determine the fact of their premature rupture, an accident which makes careful subsequent observation of the case imperative.

It may not be out of place to recall here the well-known but too often forgotten fact that the danger of sepsis is distinctly increased when the finger is carried within the cavity of the cervix or into the lower uterine segment, where the acid vaginal mucus no longer aids in inhibiting bacterial development.

The necessity for frequent examinations during the second stage is not apparent, especially if examination after rupture of the membranes shows that there is no prolapse of the cord, no extension of the head or other abnormality, and if the fœtal heart sounds are normal. The changes in the size and shape of the abdominal tumor tell that the head is low in the vagina, and the character of the pains or the condition of mother or child will indicate the necessity for interference.

A great deal of stress is usually laid on the importance of noting the progress of labor, by which is usually meant the degree of cervical dilatation, and in cases of delayed labor with possible impending maternal or fœtal exhaustion this is undoubtedly a matter of the highest importance; but in normal cases, if the head is advancing, it is pretty safe to say that dilatation is taking place, and it hardly seems necessary frequently to demonstrate this fact by measures which may endanger the welfare of the patient.

It would be interesting to pursue this subject at length, if time permitted, but it is not necessary. A brief study of the chief objects to be attained by vaginal examination will show that its employment in normal labor is much too common. It is by no means asserted that even the few examinations indicated by the above sketch are necessary in every case. Indeed, some obstetricians have felt justified in refraining altogether from internal examinations in a large proportion of cases. The physician's experience and conscience must tell him to what extent a legitimate anxiety for the welfare of his patient justifies him in interrupting a physiological process, by measures which prejudice, however slightly, the chances of a life intrusted to his care.

Those who have become expert in external palpation regard it as a more valuable means of diagnosis than vaginal examination. No unusual skill is required, but simply ordinary intelligence and perseverance. It is indeed strange that so valuable a resource should be commonly neglected, while vaginal examination is constantly practised at times when it is not only unnecessary but distinctly dangerous.

The post-partum douche, then, is not a necessity *per se*, but is given because most labors are not, properly speaking, normal. The fact that in most cases repeated examinations have been made, and too often without proper precautions, is its principal justification. The vagina is irrigated because of the possibility that sepsis has been introduced from without.

It is true that the recent experiments of Kroenig show that after the inoculation of the vagina with pure cultures of the streptococcus and other germs the destruction of these germs is not effected by an antiseptic douche given an hour later, but is actually delayed from eight to sixteen hours. These experiments, however, performed upon the normal vagina, while they show the futility of douches in most cases and as usually employed, do not apply to a recently lacerated and presumably infected surface; and it is to operative cases and to cases in which laceration of

[1] "A Treatise on Obstetrics," p. 193.

[2] "Die Entstehung der Stirn- und Gesichtslagen."

cervix, vagina, or perineum plays a prominent part that the post-partum douche seems most applicable.

A few words as to the method of giving the douche. A glass tube perforated at the sides should be used. The solution should be as hot as can be comfortably borne, but should not be too hot. As sometimes given it causes unnecessary pain and may even by constringing, if not actually cauterizing the superficial vessels, interfere with drainage, retard the necessary post-partum changes, and thus actually aid in producing sepsis. It should be understood that the object of the douche is not primarily the prevention of hemorrhage, but simply the flooding of the vagina with an antiseptic solution. A little practice will enable one to manage the tube without introducing the fingers. To distend the ostium vaginæ and carefully search the vagina and cervix for clots is to invite sepsis. Whether the air of the lying-in ward may carry the germs of puerperal infection is still perhaps *sub judice*, but there can be no doubt that freely to admit air to the vagina after delivery is the surest way to cause decomposition of coagula previously harmless.

History repeats itself in medicine as elsewhere, and the gradual substitution in obstetrics of asepsis for antisepsis reminds one forcibly of the substitution in abdominal surgery of primary closure for drainage. The latter, once considered necessary in every case, is now used only in infected cases.

From the beginning of cervical dilatation until long after delivery we have a surface favorable to the direct absorption of septic matter. How inconsistent, then, to preach asepsis in obstetrics, and at the same time advise as part of the treatment of normal cases the frequent introduction of the one instrument which we cannot sterilize—the hand, and the use of douches which serve only to interfere with the conservative and reconstructive processes of nature.

A physician of this city once said that his last seven or eight cases had been septic. He had tried in vain by the use of various methods, including the Turkish bath, to free himself from the source of infection, knowing that he carried it about with him wherever he went. Could there be a more astonishing exhibition of the influence of conservatism? A well-informed man of large experience thought it necessary to subject his patients to the practical certainty of sepsis, in order to forestall some complication which might occur once in a hundred cases, and which, even then, might be discovered by other means.

One cannot look over the obstetric literature of the day without the reflection that too large a proportion of it is devoted to the study of abnormalities and too little to the study of normal labor. It is unreasonable to suppose that the same examinations and manipulations are necessary in all cases. A sharp line should be drawn. Abnormal cases should be treated promptly and fearlessly, and normal cases should be let alone. They are dangerous only through unnecessary interference.

Diagnostic skill on the part of the accoucheur is doubtless of vast importance. Its value, however, lies not only in showing him what to do, but what not to do, and his methods of diagnosis should be, if possible, those which are devoid of risk. No less an authority than Winckel has testified to the difficulty of securing asepsis in vaginal examination. To quote from the recent text-book on obstetric surgery by Grandin and Jarman: "No matter how careful we are in our asepsis, each examination carries the risk of infection."

To sum up, the common custom of making frequent vaginal examinations during the whole course of labor is unscientific and unsafe, and it should be the aim of the conscientious obstetrician so to familiarize himself with all extravaginal methods of diagnosis as to reduce the necessity for vaginal examinations to a minimum.

All intravaginal manipulations are especially objectionable after delivery.

When the vaginal secretions are normal, ante-partum douches are unnecessary and harmful. Upon this point the researches of Leopold and Goldberg, as well as those of Fischel and others, seem to be conclusive.

In normal cases the single post-partum douche is unnecessary and therefore objectionable, but in many cases circumstances render it advisable as a precautionary measure.

The routine use of douches during the normal puerperium is contraindicated. Lusk says: "In hospital practice they have invariably increased the morbidity and the mortality rate."

It is of course to be understood that these conclusions apply only to normal cases, and in no way forbid the most searching examination or thorough disinfection when indicated.

It would be impossible to discuss this subject properly within the limits of a brief paper, but it will suffice if enough has been said to call attention to the fact that vaginal examinations in labor are far more common than they need be or should be. When women were allowed to linger in the second stage for hours, or even days, uterine inertia, post-partum hemorrhage, retained placenta, and other complications were so common as to fill the minds of writers, teachers, and students, to the exclusion of other and important matters. With the development of scientific obstetrics should come a corresponding reversal of our attitude and a modification of the methods of the last century. We should no longer think it necessary to treat all cases as though abnormal.

The ideal labor case is one in which the existence of pelvic contraction or other abnormality is disproved before labor, in which the progress of labor is observed by extravaginal methods, and in which nothing is permitted to enter the vagina after delivery. That this ideal cannot always be reached goes without saying. That we should get as near to it as we can is equally true.

Since the memorable reform of Garrigues at the New York Maternity, deaths from puerperal sepsis have been comparatively rare among us, but they are by no means unknown, while the minor degrees of sepsis occur all too often and furnish our gynæcologists with much employment. Nor will this condition of affairs be remedied until it is generally recognized that in normal labor the vagina is no more a legitimate field of experiment than the uterus.

MALARIA AND AUTOGENOUS FEBRILE CONDITIONS IN KERN VALLEY, CAL.

By REGINALD A. FERGUSSON, M.D.,

BAKERSFIELD, CAL.

It is only during the last few years that the term "malaria" has been recognized as applying to a disease with as definite a set of symptoms as any other one of the infectious diseases; the term has had a clinical rather than a pathological or etiological significance. Even yet, by some practitioners and by most of the laity, malaria is looked upon as a vague morbid influence, existing in the earth or water or air, which in a mysterious way invades the human organism and there acts as a poison, producing the most varied of symptoms and multitudinous diseases.

Of those alterations in the state of the body or of some of its organs, the result of perverted or impaired cell action—usually in this valley classed under the

term "malaria"—some are autogenous, some protozoal, and some bacterial in origin, and some are the result of two or of all these causes.

The indisposition for which the physician in Kern Valley is most often consulted is variously characterized by the following group of symptoms: Instead of the unconscious feeling of well-being that accompanies good health there is a depressed feeling with a sense of being tired and listless, and a strong disinclination to bodily or mental exertion; there is aching in the limbs and body, often markedly so in the right side and under the shoulder-blades; there are dull headache, giddiness, and disturbed and dreamful sleep; foul tongue and bad taste, especially on awakening; anorexia; nausea; stomachal cough and foul breath; sluggish and irregular action of the bowels, and the urine is often scanty, highly colored, and offensive. Accompanying these symptoms there may be, and there may not be, chilliness and fever.

The predisposing causes of these symptoms are errors in alimentation, non-adaptation of the mode of living to the habitat, and bodily or mental overwork. The pathological exciting cause which appears to correspond to these symptoms is a toxæmia due to an excessive formation of poisonous substances in the system, or an accumulation due to deficient elimination of these substances.

If alimentation errs from excess, from insufficiency, from poor quality of ingesta, in cookery, in non-adaptation to the locality and climate in which the subject lives, or if the living cells fail in the proper construction of the digestive ferments, or in the proper destruction of effete material so as to fit it for elimination by the eliminative cells, or if the functions of the excretory organs be vitiated, there accumulate in the liquids and organs of the economy various products more or less toxic.

Non-adaptation of the mode of living to the habitat always occurs among an immigrant population, and markedly so when the immigration has been from a maritime or temperate continental to a dry, hot, continental climate with a radical change in the meteorological environment. Under these circumstances there is a greater risk of exposure to extremes of temperature with the consequent production in the system of deleterious substances.

Both mental and physical labor are accompanied by the formation of toxic elements, and bodily or mental overwork causes an accumulation of these toxic elements within the system.

If the symptoms are not accompanied by fever the disease is called a bilious attack or a "touch of malaria," and if the healthy balance between the formation of and the elimination and evacuation of effete matters becomes chronically disturbed the disease graduates to "chronic malaria." If chilliness and fever are present it is called malarial fever, or if the nervous symptoms are pronounced, the opinion is expressed that "typhoid may be feared."

Of the origin and nature of the poisons which are formed in the organism itself and of their elimination and reabsorption very little is known at the present time, but that certain febrile conditions are autogenous there can be no doubt. Profuse bleeding in the healthy subject raises the temperature, probably by increasing the transudation of tissue juices into the blood-vessels. In the fatigue and exhaustion of overwork the toxæmia is caused by the infiltration into the blood from the tissues of poisonous substances, the products of retrograde metamorphosis. Overwork is a comparative term; what is overwork to one system is not overwork to another. The man of sedentary habits immigrates to this valley and becomes a farmer. He is quickly overworked at his unaccustomed toil; the result is a gradual appearance of the above group of symptoms. He diagnoses his case as "malaria," which he has heard is so prevalent in the San Joaquin Valley, and loudly lays the fault to the country and climate. The mountain farmer is taken from his plough or the cattleman from his saddle and shut up in the jury box; after a day or so of mental worry and unaccustomed sedentary life he, too, has an attack of the same malaria, and he accuses the climate of the valley as the cause. The Basque sheepman is brought to the physician, suffering with the same set of symptoms due to worry from homesickness. The business man meets with reverses; he works and worries day and night for some time; the excretory organs seem to act normally, but after a few days there are elevation of temperature and dull headache, the appetite is impaired, and sound and refreshful sleep is impossible; the brain is excited and refuses to be at rest. These are a few of the many examples which one meets in general practice of the malaise and fever of fatigue and exhaustion, and of which the pathological exciting cause appears to be an excessive formation of poisonous substances in the system and their infiltration into the circulating media.

The malaise with fever due to an accumulation of poisonous bodies in the system by reason of deficient elimination by the eliminative cells and by non-evacuation of putrefactive irritants from the intestinal canal, though not listed in our text-books, is known to all physicians, obstetricians, and surgeons of experience. There is a feeling of languor, the head aches, the tongue is coated, the breath is offensive, the bowels are torpid, and there are chilliness and fever. The physician is liable to suspect the existence of typhoid fever or malaria, and the obstetrician or surgeon fears septicæmia. It is probably the most ubiquitous complication of other diseases, and it may occur *per se*. It is one of our commonest fevers in children, in whom the power of maintaining a steady temperature is less than in adults. The predisposing causes are errors in alimentation and in the mode of life. The most common exciting cause is the invasion into the system of poisons from the intestinal canal. It is more than probable that the poisons generated in the intestines are due to the bacteria which are normally present, but this would not exclude this disease from the list of autogenous diseases. "The bacterial cells which are normally present in the intestines cannot be regarded as invaders from without." It is possible that an accumulation of tissue waste produced in the system may cause only a vital depreciation which allows the absorption of poisonous toxins, toxalbumins, and other substances from the alimentary canal, and that it is these bodies which are responsible for the febrile conditions in all autogenous fevers.

From the results of laboratory experiments there seems no doubt that the bacillus coli communis at times possesses pathogenic properties, and that by change of environment it may be brought from a condition of benignity to one of virulence. This change of environment is probably produced by errors in diet of the host, or by failure in the living cells of the alimentary organs properly to construct the digestive ferments, or failure of the canal to perform its excretory and evacuative functions.

Poisonous bodies, along with digested material, pass away from the canal, partly into the portal vessels and partly into the lacteals. In the latter case they fall into the general blood current after having undergone only such changes as they may experience by coming in contact with the lymph cells. After absorption has taken place through the intestinal walls into the blood of the portal vessels, poisonous bodies which have been absorbed will come in contact with the various constituents of the blood, and may possibly produce a depreciation in the vitality of the blood

cells, which will render them more liable to be invaded by protozoa, for example, or the poisons may remain simply absorbed in the serum. Before any poison which is absorbed from the stomach or intestines by the portal circulation can pass into the general circulation it must go through the liver. Two of the most important duties of this organ are, first, to change harmful into harmless bodies, and secondly, to turn back deleterious substances which may prove injurious to the body. Should it simply perform the latter and fail in the former, the deleterious substances are poured with the bile into the duodenum and thence may again be absorbed, so that a regular round may go on from the intestines to the liver, from the liver to the intestines and back again, for days—possibly weeks and even months—without the poisonous bodies ever getting into the general circulation. This condition may be causal of the common complaint of aching and weight in the region of the liver and also of the bitterness of the bilious vomit. Should the liver fail to perform both of the above functions, the poison is carried on to the right side of the heart, thence to the lungs, where possibly it may be eliminated or rendered harmless by oxidation; from the lungs back to the left side of the heart and on into the aorta and through the system generally, including the brain, the medulla with all the centres it contains, the spinal cord, the nerve fibres, and nerve terminations. It passes to the muscles and to the various secreting and eliminating glands, and may pass out of the body by the kidneys and sweat glands or possibly back into the intestines and stomach, for they are eliminative organs, to be again absorbed. The value of emetics and purgatives and bowel irrigation and stomach lavage is probably due to their removing not only the original putrefactive irritants but also the poisonous bodies that have been eliminated from the circulation into the digestive canal.

From clinical observation two enteric fevers occur in this valley: (*a*) an autogenous fever caused by the invasion of the system by the products of bacteria which are normally present in the intestines, but which have been changed from a state of benignity to a state of virulence; and (*b*) typhoid fever, due to infection by the typhoid bacillus. The autogenous enteric fever may present itself as a simple continued fever; its duration is indefinite and its presence probably favors the invasion of the system by hæmatozoa and bacteria. On the contrary, typhoid fever runs a more definite course and is seldom complicated by a true malarial invasion.

Personally, I class the endemic fevers of Kern County as follows:

(1) Autogenous malaise and fever due to accumulation of tissue waste in the system.

(2) Autogenous enteric fever.

(3) Protozoal fever.

(4) Autogenous enteric fever complicated with protozoal infection.

(5) Typhoid fever.

This classification is clinical and only an attempt at an etiological one, but I find that it gives me a fairly clear mental vision of the probable pathological conditions and a rational basis for treatment.

At the present time the majority of the protozoal infections in Kern Valley correspond clinically with the reported pathological conditions of the tertian parasite. Quartan fever rarely occurs. During the late summer and autumn months continued irregular fevers, somewhat resistant to quinine and with clinical manifestations fitting the reported pathologic conditions of æstivo-autumnal fever, are met with. Pernicious malarial diseases are unknown. Kern Valley is the southern part of the great interior valley of California, the San Joaquin Valley.

Progress of Medical Science.

Ergot.—Dr. Smith Ely Jelliffe in the *Journal of Pharmacology*, vol. v., pp. 73–78, "Some Notes on the Pharmacognosy of Ergot," presents a *résumé* of our knowledge of the chemical composition and the pharmacological action of this little understood remedy. He shows that modern researches in its chemistry have proven that there exist in the drug three peculiar bodies, called by their investigators "ergochrysin," "secalin," and "sphacelotoxin." The most important of these is the peculiar resinous body, "sphacelotoxin, which, however, is found in but small quantities in the drug and can be isolated with difficulty. But in combination with the other bodies above mentioned it forms more or less stable compounds, and is thus amenable to scientific investigation. With ergochrysin it forms a body called by Jacoby, a pupil of Schmiedeberg's, chrysotoxin, and with the other body, secalin, it forms a new body, secalintoxin. Chrysotoxin, which is the combination of the neutral non-nitrogenous base, ergochrysin, with sphacelotoxin, is obtained by precipitation from the ethereal extract of ergot after getting rid of the fat with petroleum spirit. It is a yellowish powder, without smell or taste, readily soluble in ether, chloroform, alcohol, and benzin; insoluble in water. On the frog's heart in doses of from 30 to 50 mgm. (½ to ¾ gr.) it acts as a gradual central paralyzant, without any convulsive action. In fowls there is a change in the circulation of the comb, which produces a violet coloration followed by dry gangrene. It also causes gastro-enteritis in fowls. In pregnant animals in doses of from 0.1 to 0.2 gm. (1½–3 gr.) it produces regular contractions of the uterus, resulting in abortion. The pharmaco-dynamical action of secalintoxin is similar to that of chrysotoxin, but is weaker, and from the evidence at hand the writer believes it to be the same as Kobert's "cornutin." Theoretically the best preparation to use would be a sodium salt of chrysotoxin.

The Diagnostic and Therapeutic Value of Lumbar Puncture.—Monti concludes as follows: 1. Tapping as a diagnostic or therapeutic adjunct is quite worthless, according to his own experiments; but it must be borne in mind that other investigators have discovered in the cerebro-spinal fluid proof positive of the tubercle bacillus, as well as cultivation in other animals, to justify the assertion that it is constantly present. His own opinion is that a negative result does not destroy a positive clinical diagnosis. 2. In acute cases of meningitis cerebrospinalis the cerebral fluid does not contain morbid products which, if applied to animals, as Heubner has shown, may serve to verify clinical observation. 3. When the acute stage has been passed and hydrocephalus is present, no diagnostic assistance can be obtained from the examination of the fluid. 4. As a therapeutic agent it is equally inefficacious in meningitis cerebrospinalis and meningitis tuberculosa. The author qualifies this by saying that individual cases do improve when operated on early and frequently, and when large quantities are abstracted. He recollects one in private practice, of two months' standing, that improved after each tapping, but ultimately proved fatal after three days' illness. 5. The writer states that his experiments are not sufficiently large in meningitis, chronic hydrocephalus, or chronic hydrocephalus in connection with tumors, to justify a critical record of their worth. 6. Further experiments are necessary to determine the quantity of fluid to be abstracted, the interval of time that should elapse between the operations, and how far the therapeutical value, if any, can be demonstrated.—*Medical Press and Circular.*

To Palpate an Appendix.—The examiner standing at the patient's right begins the search for the appendix by applying two, three, or four fingers of his right hand, palmar surface downward, almost flatly upon the abdomen, at or near the umbilicus; while now he draws the examining finger over the abdomen in a straight line from the umbilicus to the anterior superior spine of the right ilium, he notes successively the character of the various structures as they come beneath and escape from the fingers passing over them. In doing this, the pressure exerted must be deep enough to enable him to recognize distinctly along the whole route traversed by the examining fingers the resistent surface of the posterior abdominal wall and of the pelvic brim. Only in this way can he positively feel the normal or the slightly enlarged appendix. Pressure short of this must necessarily fail. —Edebohls.

An easy way is to stand on the patient's right, using three right-hand fingers to feel with and three left-hand fingers placed upon these to press with. The fingers that are to do the feeling are pressed by means of the three others down under the border of the right rectus abdominis muscle at the level of the navel, and slowly drawn toward the examiner. My sole landmark, the ascending colon, is then felt to slip out from under the fingers, and by repeating the process toward the cæcum we soon come to the end of the cæcum, and there begin to hunt for the appendix by rolling the cæcum from one side to the other of the finger tips. The proximal end of the appendix is found near the distal extremity of the cæcum, and we then follow the rest of the appendix in any direction. The proportion of appendices that cannot be palpated will become smaller and smaller as the finger tips become educated. The point about using no muscular effort in the hand that is to be used in feeling is as important in palpating appendices as it is in palpating ovaries and tubes. The very delicate sense of touch is preserved if the left hand is used for pushing upon the examining hand. —Robert T. Morris, "Lectures on Appendicitis," p. 43.

The Conservative Agency of Shock.—Dr. H. G. Wetherill (*Journal of the American Medical Association*, March 12, 1898), in an article on this subject, deduces the following conclusions: 1. Surgical shock entirely unassociated with hemorrhage is a condition rarely seen, and one which may usually be successfully treated in persons who are otherwise in good health. 2. Hemorrhage, though small in amount, is a far more important factor in the production of surgical shock (as it is seen clinically) than we have been accustomed to think it. 3. This mixed shock (traumatic asthenia) should be designated by some distinctive title, or the term shock be construed to comprehend all the factors in its genesis. 4. While not proven, it seems probable that the effects of even a small continuous arterial hemorrhage is to produce through its reflex action lower blood pressure, and in general a condition so like true shock as to be very difficult of differentiation, particularly if the hemorrhage is concealed; as in ruptured ectopic pregnancy. 5. Surgical shock, with or without hemorrhage, must be construed as primarily conservative in its tendencies. The incident prevention of rapid exhaustion, of acute suffering, or great blood loss when the blood-vessels are opened, all tend to the ultimate saving of life. 6. Premature stimulation in the treatment of traumatic asthenia may defeat this conservative effort of nature. Bleeding should be stopped and proper provision made for the comfort and welfare of the patient before strong stimulation is resorted to, unless there is imminent danger of death. 7. Anæsthetics must be sparingly and carefully given to patients suffering from surgical shock (traumatic asthenia), chiefly because they completely obliterate the reflexes. The saturation of the patient with an anæsthetic may turn the scale against him, even though the direct effect of the anæsthetic be stimulant. The same rule holds good in regard to the employment of alcoholic stimulants if too freely used. 8. We should co-operate with and supplement nature's conservative efforts. They are always exercised in behalf of the patient, never against him.

Bacelli's Treatment of Tetanus by Carbolic-Acid Injections.—Dr. V. Ascoli carries out Bacelli's treatment in the following manner (*Academia Medica*, Rome, March, 1898): 0.03–0.04 gm. of carbolic acid, in the form of a two to three per cent. solution, is injected subcutaneously, so that the patient receives 0.35 gm. of carbolic acid a day. No deleterious effect need be feared. The symptoms of tetanus become rapidly less and weaker, and as soon as the injections are stopped the symptoms again become violent. Out of five patients the speaker has thus treated, four recovered, one died. One of these came under treatment on the eighth day, and had severe respiratory and circulatory disturbances; during his whole course of treatment (one month) 15 gm. of carbolic acid were injected. In another case 14 gm. of the acid were injected in fourteen days. At present there are thirty-one reported cases treated by this method, of which number only one was fatal. Comparing this treatment with that by serum injections (tetanus neonatorum is not counted), we have the following: Bacelli's treatment, 1 death in 30 cases; Tizzoni's serum, 8 deaths in 40 cases; Behring's serum No. 1, 4 deaths in 11 cases; Behring's serum No. 2, 2 deaths in 9 cases. The speaker explains the large amount of carbolic acid being injected without causing any symptoms of toxæmia by the peculiar resistance of tetanus patients against this poison.

To Prevent Rigors of Urinary Fever.—C. Mansell Moullin says in *The Lancet*, that the strongest argument in favor of the septic origin of these rigors is the fact that they can be prevented by adopting suitable antiseptic measures. The first essential is to clear out the intestinal canal thoroughly. For some days the patient should be given two or three grains of salol six or eight times in the twenty-four hours. If the urine is alkaline from the presence of a fixed alkali, benzonaphthol is to be preferred, given in cachets, as it breaks up in the intestine into betanaphthol and benzoic acid. Three days before the operation the patient should be given a calomel purge, followed by an effervescing draught, and again the night before. Immediately before the operation the glans penis, prepuce, and meatus should be thoroughly washed with soap and water, and then with corrosive-sublimate solution (1 to 1,000). The urethra itself must be cleansed with a boric-acid douche and a catheter that admits of a return current along the walls. Pass the catheter into the fossa navicularis and wash that out thoroughly, then push it in a little farther and repeat the process, and finally carry it down to the face of the stricture. At the end of the operation the bladder should be emptied by means of a catheter, and two drachms of a two-per-cent. solution of nitrate of silver injected into the deep part of the urethra and on to the face of the stricture and left there. The nitrate is decomposed at once into the chloride, which is thrown down as an insoluble powder on the surface of the mucous membrane, acting as an effectual germicide. Micturition should be postponed for as long as possible after the operation, in order that the surface of the wound may become glazed over, and the patient should not be allowed under any circumstances to get out of bed or expose himself to the least chill.

Pyonephrosis or Renal Congestion ?—Dr. Loumeau reports the case of a woman who had suffered for a long time with an intense cystitis and enormous vesical calculus and uretero-pyelitis; the two kidneys were large and painful, the right more so than the left. At the same time there was evening fever, with dryness and icteric tint of the skin, emaciation and extreme general prostration, and very purulent and fetid urine. The calculus was removed by the vaginal route, and the wound was left in a fistulous state in order better to insure the permanent drainage of the bladder and the ureters. The persistence of renal tumefaction and of the general symptoms indicated the existence of a double pyonephrosis, more developed on the right side. The right kidney was opened by the lumbar route fifteen days after the vesical intervention; it was large and reddish-purple, but neither dilated nor purulent. It was immediately closed with a catgut suture, and the wound was completely healed at the end of eight days. This was not, as was erroneously supposed, a pyonephrosis, but simply a renal congestion. At the end of a few weeks it had entirely disappeared—as well on the left side, which had not been operated upon, as on the right side, which had been operated upon.

Appendicitis.—In an address delivered by Dr. John Fife, president of the California Northern District Medical Society, at its seventh annual meeting, he said: "Certainly appendicitis does subside without the removal of the appendix; and it does so in a very large percentage of cases; nor does it always recur. Indeed, it recurs in but a small percentage of cases. In short, the real dangers of appendicitis—and they are great—have been multiplied. All are agreed that in suppurative cases, in recurring and in fulminating cases, operation is imperative. The controversy over the question has recently waxed quite warm in the East. The defenders of medical treatment have presented their views at much length, and have offered their statistics to substantiate them. The surgeons have examined them, and have first doubted and then sneered at the diagnoses, and in turn have presented their statistics, which certainly reflect credit both upon their operative skill and upon the efficacy of asepsis in surgical work. But it should not be forgotten that the same degree of skill, the same perfection of aseptic conditions and surroundings, and the skilled nursing are rarely to be had outside the hospitals of cities, to say nothing of the fact that because an operation is successful it does not follow that it is necessary. Time is necessary in order to define the limits of the operation. Meantime the wise general practitioner will operate only when operation is plainly indicated."—*Occidental Medical Times.*

Treatment of Abdominal Contusions.—Dr. Eugene St. Jacques says that there are a number of means of combating shock in general and internal hemorrhages, of calming any pain present, of mobilizing the wounded region or the affected organs, the aim of all of which is to favor natural cure and to prevent complications, or to cure these complications if they should arise. Stimulants, injections of different serums, ether, or caffeine, absolute rest, diet, ice internally and externally, opium in all its forms, and different medical treatment according to the indications of the morbid state, form the basis of these methods of treatment. "In the presence of a very severe shock or of a very light one, there is unanimity in regard to the means to be employed. We have succeeded in obtaining a cure in extensive tears or rents of the liver, spleen, and kidney. But agreement ceases in doubtful cases." Among the surgeons who took part in the discussion of Dr. St. Jacques' remarks was Le Dentu, who said that, except in cases of rupture of the kidney or bladder, the direct diagnosis of visceral lesions caused by abdominal contusions is open to numerous chances of error. In doubtful cases some wish a purely medical treatment; a second class refuses surgical intervention as long as the peritoneum shows no inflammation, or as long as collapse is not imminent; another class resorts to laparotomy as soon as the symptoms appear to be in the least serious. Le Dentu holds that a purely exploratory laparotomy is justifiable whenever the diagnosis is doubtful and circumstances permit *a priori* the possibility of visceral lesions. Intervention ought to be as hasty as possible, the least hemorrhage necessitating immediate action, but in general it is well to allow the wounded patient an hour or two to recover from the violence of the initial shock.

The Tuberculin Test.—Mr. Cameron, veterinary inspector to the board of health of Victoria, has presented a report showing the result of his experiments with tuberculin as a test for tuberculosis in dairy cattle. If properly applied he believes it never fails. Characteristic experiments were made on the herds at the Leongatha labor colony. A number of cows reacted to the test, and, being slaughtered, were all found to have tuberculosis. Forty showed no reaction and fifteen months later were again subjected to the test and showed no reaction. Two were slaughtered and found to be free from tuberculosis. Mr. Cameron is satisfied that if all dairy herds were tested, and the animals infected were condemned and slaughtered, tuberculosis in cattle could be easily stamped out.—*The Lancet.*

The Radical Cure of Congenital Hydrocele.—Dr. Menciere (*Archives Cliniques de Bordeaux*) reports two cases of congenital hydrocele in which the following operative method was used with perfect satisfaction. The operation consists in making a long incision along the long axis of the tumor; that is to say, from above downward, the incision being prolonged to the inguinal ring. The serous membrane should be freely incised, as is done in the method of Volkmann. The peritoneal-vaginal canal should be destroyed by cutting transversely through it with the scissors. The edges of the serous sac thus formed should be brought together and sutured with catgut in such a way that the testicle will be contained in a reconstructed vaginalis, smaller than the first. Above this new vaginalis the serous membrane should be cut to a certain height, so that the peritoneal-vaginal canal will be destroyed beyond a doubt. Then, considering the superior part of this canal as a hernial sac, proceed with the radical cure of hernia. The inguinal ring is closed, the portion of the peritoneo-vaginal canal immediately beneath is destroyed—that is, excised; the testicle is contained in a new vaginalis smaller than the first, whose walls have been destroyed according to the method of Volkmann, the cavity not having ulteriorly any communication with the abdominal cavity. This method, differing from that described by Faure and from that which consists in simply practising a radical cure as in a hernia, is habitually employed. Here the author is not content with opening the vaginalis and reckoning on an adhesive inflammation to obliterate the peritoneo-vaginal canal. The surgeon should not only destroy the canal, but should also close the inguinal ring. Again, instead of leaving the vaginalis to repair itself, as one does after operating for the radical cure of hernia, catgut sutures are employed to reconstruct it immediately. The operator can, with impunity, reconstruct the vaginalis and afterward close the inguinal ring; but in the case of congenital hydrocele accompanied by hernia it is preferable to close the inguinal ring first, as indicated, and then proceed to repair the vaginal cavity

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

HYSTERECTOMY FOR CANCER OF THE UTERUS.

THE first extirpation of the prolapsed uterus for cancer is said to have been performed in 1560 by Andreas A. Cruce. The non-prolapsed uterus was removed per vaginam for the first time in 1822 by Sauter, of Constance. In 1829 Recamier placed the operation on a scietific footing by ligaturing the base of the broad ligaments, while the credit of having made the clamp a practical success belongs to Péan and Richelet. To such a degree of efficiency has the operative treatment of uterine cancer been brought that the palliative treatment, although still advocated by some well-known surgeons, has ceased to be in favor with American and English operators. The only valid argument against hysterectomy is the difficulty in making a diagnosis in the early stages of uterine cancer. The mortality from operations has diminished, but the fact is still with us that the cancerous disease has too often advanced beyond the uterus before the radical operation is performed, and many cases when presented are inoperable, at least by the vaginal route. Thus the necessity for early and frequent examination is strongly indicated.

The records of some of the European operators on cancer of the uterus are so phenomenal as almost to give rise to feelings of doubt. For instance, Hofmeier declared that thirty-three per cent. of his patients were in perfect health four years after operation; Schauta, of Prague, claimed forty-seven per cent. of complete recoveries two years after operation; Olshausen, of Halle, forty-seven and one-half per cent. without recurrence in two years; while Leopold had the remarkable record of seventy-two patients, out of a total of seventy-six, still alive and in absolute health from one to five and one-half years after operation. Although no American surgeon can show results so successful as the foregoing, yet many can point to very satisfactory records.

Dr. Emory Lanphear, of St. Louis, has recently published in the *American Journal of Surgery and Gynecology* a report of the cases operated upon by him, and states that his total number of hysterectomies has been 109; of the patients 7 have lived more than six years, 13 more than five years, 12 more than three but not yet five years; 15 died from the operation or soon after, 1 died from recurrence after three years, 7 died from recurrence before three years; 2 were living with recurrence after three years, 6 were living with recurrence before three years. The total number of recurrences known was 16, and of recurrences suspected, 10. One died from other causes without recurrence after five years, and 3 died from other causes without recurrence after three years. Thirty-two were lost sight of or were still in the danger period at the time of the report. These figures show a primary mortality of 14 per cent., but the mortality of the last 31 cases under recent careful methods of operating was only 6 per cent. Dr. Lanphear argues that even if his 7 patients who have now lived more than six years should prove to be the only ones truly cured of the entire list, the 109 operations were fully justified, and if the 20 who have passed five years are considered, the question must be favorably answered, even by the most conservative. Dr. Lanphear concludes his paper with the following rules as to when hysterectomy is not indicated: (1) Whenever the disease is so far advanced that the uterus is fixed in the pelvis; (2) whenever it is certain there is extensive cancerous infiltrate in the broad ligament; (3) whenever the cancer involves the bladder; (4) when the "cancerous cachexia" has become pronounced; (5) when the patient is too weak from repeated exhausting hemorrhages; (6) whenever the diagnosis of sarcoma of the uterus is quite certain. In such cases there is always recurrence after removal, and the patients die quickly.

THE NEGRO DEATH RATE.

THE physical degeneracy of the Afro-American race is a self-evident fact that can no longer be ignored or explained away. The educated negro is compelled to acknowledge that since the abolition of slavery there has been a rapid increase in the rate of mortality among the colored people. This confession is in itself an excellent sign and augurs well for the future. It is much the better policy boldly to face ills than to brush them aside and stigmatize them as the inventions of enemies.

At a conference recently held at Hampton by leading members of the negro community the keynote pitched was the thorough appreciation by the speakers of the real situation. The most able paper presented to the meeting was one contributed by Dr. Furness J. Shadd, of Washington, his subject being "A Remedy for the Excessive Mortality of the Negro." After pointing out that, even under the most favorable sanitary conditions, the death rate of negroes is more than double that of whites, Dr. Shadd says: "Negro mortality must be reduced, is the watchword of every intelligent person. While we deplore the promulgation of facts which are detrimental to us, yet the end will justify the means. We must have results, not sentimental speculation. Among the most fruitful causes of this alarming death rate are the following: Infant mortality, tuberculosis, scrofula, specific infection, gastro-intestinal diseases, heredity, and environment. Most of these conditions can be changed by the negro himself without the aid of outside influences. Only those persons who come into intimate contact with

the colored people can fully appreciate their racial traits and characteristics. Only after very careful inspection should we attempt to answer as to the social problems affecting the vital conditions of the negro to-day and his conditions in the future. My observation leads me to believe that more factors inimical to the race are found within than without."

With regard to the great susceptibility of the negro to consumption, Dr. Shadd remarks: "Consumption is the greatest enemy the negro has except his vices. . . . My experience teaches me that the negro cannot stand local tuberculous infection without running great risk of pulmonary complications, and, furthermore, I think that the mulatto is more susceptible than are the blacks." The author then touched upon the manner in which negroes live in the large cities, and said: "The condition of the negro in all the large cities is a theme worthy the attention of each of us. I know him as he is under the shadow of the goddess of liberty within the District of Columbia. The habits, the disposition, the clannish congregation of most of the race, compel them to inhabit parts of the city densely populated, from which they may easily go at all hours of the night from house to house, from church to church, to meet kindred spirits, whose only aim in life is to eke out a mere living, with sufficient time after work for the gratification of their pleasures. Hence we find them living in alleys and courts, where families of more than a dozen often occupy very narrow quarters. The sanitary conditions of these houses are frightful. Can we wonder that death claims many who are so situated?" Dr. Shadd winds up his interesting contribution with the statement that, in his opinion, heredity plays the most prominent part in the physical retrogression of the colored race. The paper, emanating from an Afro-American, and one who is besides scientifically familiar with his subject, is highly instructive, and should tend to bring in vivid colors to the perceptions of both white and black that the unhappy condition of the negroes is a public menace, and should incite philanthropists to grapple more energetically with the difficulties of the situation than has hitherto been the case.

MALARIA AND ENVIRONMENT.

Laveran's discovery of the hæmatozoon malariæ is believed by the majority of medical investigators to have settled the question of the pathology of the malarial fevers. There are still, however, some sceptics who are unwilling to admit that such is the case, and who contend that the cause of malaria is environment. Among these unbelievers is Dr. M. D. O'Connell, a surgeon in the British Indian army, who has recently published a pamphlet upholding his views. He asks the question, "Can environment cause malaria?" and answers it in the affirmative for the following reasons: 1. The meteorological environment under which ague becomes prevalent is a hot, moist, stagnant atmosphere. 2. Exposure to this malarial environment produces an intermittent increase of water in the blood. 3. Intermittent increase of water in the blood in ague reduces temperature to normal; the increase of temperature in malaria produces: (*a*) wholesale destruction of red blood corpuscles; (*b*) increase of pigment, free or inclosed in bodies of various shapes, melanæmia; and (*c*) enlargement of the spleen."

The writer next points out a definite and appreciable condition of the blood which will cause some to contract ague in climates not considered malarial, while others will not do so in the most malarial climates. Dr. O'Connell's reasoning in support of his opinions, though plausible and intelligently thought out, is too elaborate and lengthy to treat in full; but in brief his theory is that ague is produced by an excess of water in the blood due to environment, as opposed to Laveran's plasmodium theory. Nevertheless, in view of the recent brilliant work done by Ross in support of the parasitic origin of malaria, it may be said that Laveran's discovery now stands on a firmer basis than ever. In fairness to Dr. O'Connell the fact should be mentioned that, while he holds that ague or intermittent fever is caused by environment, he does not believe that remittent or other form of malarial fever is due to this cause.

ZOLA A NEUROPATH.

Anthropology—thanks to the labors of Lombroso and other scientific men of the Italian school—occupies a much more prominent position than was at one time accorded to it. Max Nordau's startling theory that genius is only a form of degeneration, although not accepted in its entirety, is yet regarded by many as worthy of some consideration. Until recently no genius has offered himself as a subject for investigation. Now, however, Zola has stepped into the breach and has allowed a thorough study of himself to be conducted by a number of French specialists. Whether Zola can be looked upon as a genius is a point upon which probably no two persons will agree, but that he is possessed of abilities far above the average will be conceded by all; and that he has, judging from his writings, many of the mental attributes of degeneration, will also not be denied. It appears from the investigations, the results of which are published in a pamphlet by Arthur MacDonald, that physically Zola is somewhat abnormal, but not peculiarly so; that he is neither epileptic nor hysterical, nor is there the slightest sign of mental alienation. Although he has many nervous troubles, the term "degeneracy" does not apply to him wholly. Magnan classes him among those degenerates who, though possessing brilliant faculties, have more or less mental defects. It is true that Zola has orbicular contraction, cardiac spasms, thoracic cramps, false angina pectoris, sensory hyperæsthesia, obsessions, and impulsive ideas; his emotivity is defective, and certain of his ideas are morbid; but all this is not sufficient to affect in any appreciable manner his intellectual processes. His strong and harmonious constitution give him immunity; his intellect is not contaminated. Toulouse says he has never seen an obsessed or impulsive person who was so well balanced. Yet Zola is a neuropath —that is, a man whose nervous system is painful.

Heredity seems to have caused this tendency, and constant intellectual work to have affected the health of his nervous tissues. Now it is a question whether this neuropathical condition is not an excitation that has given rise to the intellectual ability of Zola; whether a diseased nervous system is a necessary cause of great talent or genius is quite another question. Yet pathological facts have been such constant concomitants of great talent and genius that the relation seems to be more than a temporal one, and suggests the idea of cause and effect. However, before this burning question is finally decided, it will be necessary to make a study of several other geniuses.

News of the Week.

A Gift to the Cornell Medical College. — Mr. Oliver H. Payne has given $1,500,000 to Cornell University for the benefit of the newly established medical department in this city. The money goes for the purchase of land, the erection of a building, and a liberal endowment. A plot of ground on the west side of First Avenue, running from Twenty-seventh to Twenty-eighth Streets, has been purchased, and a five-story building will be erected on it. Work on this will be begun almost immediately, and the building will be ready for occupancy in a year from this time. The faculty of the new college is substantially the old faculty of the University Medical College. As the result of a controversy with Chancellor McCracken and some of the trustees of the university, the medical faculty resigned and united with Cornell, to found a medical department of that university. Mr. Payne, who was one of the trustees of the university, and who some years ago gave $150,000 to the medical school, sided with the medical faculty in the dispute with the university authorities. The full four-year course of the Cornell University Medical College will be given in New York, and the course of the first two years will also be given in Ithaca. Men students may take half the course in Ithaca and the other half in New York, or the entire course in New York; women students must take the first half of the course in Ithaca (where a home is provided in the Sage College for women) and the last half in New York.

A New Journal.—We have received the first number of *The Psychiater*, a quarterly journal published by the medical staff of the Illinois Eastern Hospital for the Insane, and intended to contain reports of clinical observations and investigations in the microchemical, pathological, and psychological laboratories of this institution. The first number contains the following papers: "Professional Work in Hospitals for the Insane," by William G. Stearns, M.D.; "Report of Three Cases of Brain Tumor with Special Reference to the Pathology of Neuroglioma and the Psychical Changes Caused by Brain Tumors," by A. F. Lemke, M.D.; "The Early Diagnosis of Paretic Dementia," by V. Podstata, M.D.; and "Laboratory Psychology as Applied to the Study of Insanity," by William O. Krohn, Ph.D.

Camp Wikoff has been again investigated, this time by Deputy Surgeon-General Charles Smart, and pronounced good. He says that the site of the camp is excellent, the soil is firm and compact, the sanitary conditions are good, and there is no danger of an epidemic of typhoid fever. Dr. John W. Brannan, of this city, recently called the attention of President McKinley to the inhumanity of shipping soldiers ill with typhoid and malarial fevers from Montauk to Long Island City, and suggested that the soldiers about to go away on furlough be inspected by the surgeons before being allowed to leave the camp. As a result of this the barbarous business, such as was described by Dr. W. Gilman Thompson in the MEDICAL RECORD of last week, has practically ceased.

The Hospitals at Camp Thomas.—Generals Sanger, Mattocks, and Roe, who were recently at work at Chickamaugua as a hospital and camp examining-corps, report that the conditions in the various hospitals were found to be very unsatisfactory. They state that the hospitals were not provided with the proper necessities, that they did not have a sufficient number of attendants, that they were badly located, and that they were in every way inadequate. Major Ward, brigade surgeon at Camp Thomas, has made a statement in which he is reported to have said that the hospitals were poorly managed and great suffering resulted. The cause for the lack of care of the sick was the want of everything that goes to make up proper hospital equipment. The number of patients in the hospital was more than double what it should have been. "The endless red tape necessary to go through with an order to secure supplies and hospital equipment made it impossible to meet such an emergency as had to be met at Camp Thomas. There was never at any time during the first two months a single hour that there were cots, tents, medicines, nurses, or food sufficient to meet the demands of those suffering men. The prescriptions had to be made to fit the medicines on hand instead of the needs of the patients." It is difficult to fix the responsibility for this condition of things. Red tape is chiefly to blame, army officers refusing to pay attention to requisitions for supplies unless they filled all the technical requirements in every way.

A War Department Investigation.—President McKinley has decided to appoint a committee to examine into the conduct of the commissary, quartermaster, and medical bureaus of the war department during the war, and into the extent, causes, and treatment of sickness in the field and in the camps. In his letter to those asked to serve on the committee he says that it is his desire that the full and exact truth shall be ascertained and made known. Dr. W. W. Keen, of Philadelphia, is mentioned as the medical member of the committee, and is reported to have accepted the President's request to serve. Several of those who were asked to serve have declined.

Cocaine is much less frequently employed in dental practice than formerly, and the strength of the solutions employed has also been reduced. Ten-per-cent solutions were commonly used some years ago, but now a two-per-cent. strength is seldom exceeded.

General Wood's Sanitary Work.—The city of Santiago, long known as a breeder of pestilence and one of the dirtiest and most unhealthy places in dirty and unhealthy Cuba, has been in American hands only about two months, and is now in a condition of cleanliness that New York might almost have envied a few years ago. Under the system introduced by General Wood, who, it may be remembered, is a physician, Santiago is divided into five sections, each one under the general supervision of a medical man, who has under him inspectors of sewers, streets, houses, and dispensaries, and a number of street cleaners. Five hundred cubic yards of refuse are burned daily, disinfectants are distributed wherever they are needed, and a heavy fine is imposed for uncleanliness or for any failure to report unhealthful conditions and deaths. The results are shown in a decrease in the death rate within a month from an average of seventy to one of twenty a day. Among the troops the principal diseases are typhoid, malarial, and yellow fevers, and dysentery. The cases of yellow fever, several of which have been among the so-called immunes, are few in number and the disease is of a very mild type. The mortality from malaria or dysentery is much greater than that from yellow fever. Now that the Spanish troops have all left for Spain, it is hoped that yellow fever can be made still less dangerous through the continuance of Dr. Leonard Wood's good work.

The Utility of First-Aid Packets.—In a report of the medical work at Santiago, made to the surgeon-general by Lieut. Guy C. M. Godfrey, assistant surgeon, United States army, commanding officer of the hospital corps, company F of the first division of the fifth army corps, the writer says that during the battle the first-aid work was very effective and was done mostly by regimental surgeons and their hospital squads. Many dressings were applied by the line officers and soldiers on the firing-line, and in some instances by the wounded men themselves. Major S. Q. Robinson, who commanded the Aguadores dressing-station on July 1st, says that only about ten patients came there who had not been dressed by first-aid packets. Words can hardly express the appreciation which the officers and men of the line have for the first-aid packets. They realize now as never before the value and importance of instruction in first-aid work. The very small number of suppurating wounds can readily be accounted for by the prompt application of these dressings.

Dr. Archibald D. Busby, assistant surgeon of the seventy-first regiment, is at the home of his sister in this city, ill with typhoid fever. He was detailed to care for the members of the regiment who were too sick to leave Santiago with the organization, and arrived in New York only a week ago, having reached Camp Wikoff on the transport *Missouri*.

Winter Hospitals for the Troops.—Workmen have been busy for some weeks, under the direction of the army medical department, erecting a hospital on the government reservation at Fort Monroe, and Lieutenant-Colonel Woodhull, the surgeon in charge, has reported that the hospital is now ready for the reception of troops. There is already at the fort a tent hospital, capable of accommodating five hundred patients. The new hospital is built of wood and contains accommodations for one thousand patients. It is intended for the reception of sick soldiers returning from Porto Rico. Looking ahead to the possibility of an extended occupancy of Cuba by the United States army, Surgeon-General Sternberg is planning for another hospital on an even larger scale at one of the Southern ports, more accessible from Cuba, probably Charleston or Savannah. He has appointed a medical board to make an inspection of the available places, and as soon as a site is selected work will be begun on the buildings.

He's a Real Good Prince.—We are pleased to learn on the best authority that during the past fortnight the progress made by H.R.H. the Prince of Wales has been very gratifying to his surgeons. Indeed, during the five weeks and a few days which have now elapsed since the accident nothing has occurred to interrupt the progress of the case. The local conditions are all satisfactory. . . . The prince is fully aware of the long interval which must ensue before the repair of the injury he has so unfortunately sustained is thoroughly accomplished and is quite prepared to submit to all the restrictions which the need for incessant care entails. The fortitude, good temper, and patience that he has shown under circumstances so trying are admirable, and we feel sure he possesses the sincerest good wishes and sympathy of the entire community.—*The Lancet.*

The Plague in India.—The number of deaths in India from the plague, during the present epidemic, has now passed the one hundred thousand mark. This is only the number of deaths officially reported. It is well known, however, that a great many cases of the disease are never reported, and even the deaths are concealed, being attributed to fever and lung complaints. Hitherto the disease has spared Europeans, with the exception of nurses and others in close attendance on the plague-stricken, but the deaths of two English ladies at a small place on the Western Ghats have caused alarm as suggesting the possibility of an extension of the disease to others than natives. The problem how to fight the plague without offending the religious prejudices of the natives is puzzling the authorities. The natives argue that the system of public hospitals has proved intensely distasteful to all classes, and that some other method must be tried if the officials are to secure the co-operation of the people. In certain villages good results have been obtained by removing the population from an infected area, but this is obviously impossible in capitals like Calcutta or Bombay.

Tri-State Medical Society.—The tenth annual meeting of the Tri-State Medical Society of Alabama, Georgia, and Tennessee, will be held at Birmingham, Ala., Tuesday, Wednesday, and Thursday, October 25, 26, and 27, 1898. The president of the society is Dr. J. A. Goggans, of Alexander City, Ala., and the secretary Dr. Frank Trester Smith, of Chattanooga.

The New York State Medical Association.—The following is the preliminary programme of the annual meeting of this association, to be held in this city on October 18th, 19th, and 20th: "A Practical Demonstration in the Reduction of Infantile Mortality," by Dr. E. F. Brush, of Mount Vernon; "The Pneumogastric Nerve in the Production of Stomach Disease," by Dr. Julius Pohlman, of Buffalo; "The Coccyx," by Dr. J. E. Walker, of Hornellsville; "Drugs *versus* Cardiac Insufficiency," by Dr. O. T. Osborne, of New Haven; "The Passing of Alcohol," by Dr. J. M. Farrington, of Binghamton; "A New Method of Amputation at the Knee-Joint, Applicable in Cases of Senile Gangrene of the Foot," by Dr. Stephen Smith, of New York; "Anthropological Rambles in the Orient, Especially in the Island of Java; Profusely Illustrated with Stereopticon Views," by Dr. H. Ernst Schmid, of White Plains; "Dental Pathology in its Relationship to General Health," by Dr. Dwight L. Hubbard, of New York; "Subnormal Temperature," by Dr. Leroy J. Brooks, of Norwich; "Ancient and Modern Animal Products Used as Medicines," by Dr. T. J. Acker, of Croton-on-Hudson; "The Treatment of Cases of Pulmonary Tuberculosis that Cannot Go away from Home," by Dr. Delancey Rochester, of Buffalo; "Some Observations of General Interest Regarding the Course and Management of Cataract," by Dr. J H. Woodward, of New York; "Technics and Use of Saline Infusion," by Dr. Thomas F. Reilly, of New York; "What to Do to Be Saved, Being the Conclusion of the Inquiry into the Abuse of Medical Charity," by Dr. Thomas J. Hillis, of New York; "True and False Medical and Other Charities," by Dr. Wickes Washburn, of New York; a paper by Dr. Charles Phelps, of New York, title not yet announced; "Genital Neuralgia and the Genito-Reflex Pains," by Dr. F. P. Hammond, of New York; "Lantern-Slide Exhibition," by Dr. S. Alexander, of New York; "A Case of Attempted Obliteration of the Deformity in Pott's Disease," by Dr. Charles Allen Tuttle, of New Haven; "Notes on Neuralgic Affections of the Head," by Dr. Gustavus Eliot, of New Haven; "The Use of Catgut Sutures in Ventrofixation of the Uterus," by Dr. J. E. Janvrin, of New York; "Traumatic Tetanus—Report of a Case Following an Attempted Operation, Treatment, etc.," by Dr. Z. J. Lusk, of Warsaw; "Some Thoughts on Rational Treatment of Disease," by Dr. Chauncy P. Biggs, of Ithaca; "Senility," by Dr. F. W. Higgins, of Cortland; "A Case of Extra-Uterine Pregnancy Operated upon at Term," by Dr. Eli Van de Warker, of Syracuse; "Memoranda," by Dr. H. D. Didama, of Syracuse; "Diagnosis and Surgical Treatment of Renal Calculus," by Dr. N. Jacobson, of Syracuse; "Eye Lesions in Some Diseases of the Kidney," by Dr. H. S. Oppenheimer, of New York; "Insanity Following Surgical Operations," by Dr. W. D. Granger, of Bronxville; "Dermoid Cysts of the Ovary," by Dr. C. E. Fritts, of Hudson; "The Operative Cure of Inguinal Hernia in Men," by Dr. E. D. Ferguson, of Troy; "Urethral Stricture," by Dr. J. W. S. Gouley, of New York. A discussion on intestinal obstruction will comprise the following papers: "Introduction," by Dr. Parker Syms, of New York; "The Causes of Acute Intestinal Obstruction, with the Description of their Mechanism," by Dr. E. D. Ferguson; "The Causes of Chronic Intestinal Obstruction, with a Description of their Mechanism," by Dr. J D. Bryant, of New York; "Intestinal Osbtruction Due to Impaction of Fæces, Gall Stones, Foreign Bodies, etc.," by Dr. J. W. S. Gouley; "The Diagnosis and Indications for Treatment of Acute Intestinal Obstruction," by Dr. J. D. Rushmore, of Brooklyn; "The Diagnosis and Indications for Treatment of Chronic Intestinal Obstruction," by Dr. Leroy J. Brooks; "Intestinal Obstruction Due to Intussusception and Volvulus," by Dr. John F. Erdmann, of New York; and "The Technic of Operative Treatment of Intestinal Obstruction," by Dr. Frederick Holme Wiggin, of New York.

The Responsibility for Injuries Resulting from Hazardous Employments.—A case is reported in the New York *Times* of a man, who was employed as assistant engineer in white-lead factory in Brooklyn, who recently brought suit against the company, charging that, while the business carried on by it was dangerous to the life and health of those employed, the company failed to inform him of such danger, but, on the contrary, told him there was no danger. The plaintiff asserted that he was ignorant of any such dangerous effects, and that his system became thoroughly permeated, impregnated, and saturated with lead poison, so that at the end of a year he was permanently disabled from work. A judgment given in favor of the defendant on the trial has been affirmed by the second appellate division, which held, in an opinion by Presiding Justice Goodrich, that a "person employed in a white-lead factory takes the risk incident to the employment. Where the common knowledge of men and a constant opportunity to see the precautions which were observed in the factory, some of which Berry was directed to observe, the sickness of workmen, and the notice that there was danger from lead dust, showed that he possessed knowledge of the conditions and consequences of his employment, the fact that during the course of such employment he was stricken with paralysis gives him no right of action against his employer. The fact that only two cases can be found in the records of the State in which an action has been brought upon such ground offers a strong presumption that actions of this character are not maintainable."

Texas Fever in California.—It is reported from San Bernardino, Cal., that Texas fever has broken out among the cattle on the Mojave River, near Rock Springs. The supervisors have ordered the county veterinary surgeon to visit the locality, to investigate the report. It is said that the disease was brought from the coast counties.

Dr. William L. Rodman, lately of Louisville, has accepted the chair of surgery in the Medico-Chirurgical College of Philadelphia. He occupied that chair, as well as the chair of surgery in the Kentucky School of Medicine, last year, but has now resigned the latter.

The Assassination of the Empress of Austria.—A post-mortem of the murdered empress has shown that the blow of the assassin broke the fourth rib, the weapon piercing the lung and the left side of the heart and penetrating three and one-third inches. After being stabbed the empress walked to the steamer, a distance of fifty yards, and it was only after reaching the vessel that she fell. The wound in the heart muscle was only a sixth of an inch in length, and the elasticity of the myocardium partially closed this and prevented an immediately fatal loss of blood.

Koch Going to Study.—It is reported that Professor Koch has at last awakened to the fact that his alleged discoveries regarding malaria were discovered long ago, while he was making tuberculin; he has accordingly gone to Italy to spend several months in the study of malaria, and is at present working in the hospitals at Rome. The results of his investigations, remarks an English contemporary, will be awaited with much interest, for it must be confessed that some of his recent utterances on this subject have caused no little surprise, since they appear to have been founded upon a somewhat hasty inquiry.

Obituary Notes.—Dr. Eugene S. Forman, of Auburn, N. Y., died suddenly of apoplexy on September 13th, at the age of fifty-one years. He was a graduate of the medical department of the University of Buffalo in the class of 1870.—Dr. George Trowbridge, of this city, died suddenly on September 10th, at the age of forty-three years. He was a graduate in arts of Yale College in 1878, and in medicine of the College of Physicians and Surgeons in 1881. He retired from practice some years ago.—Dr. E. S. Tyner, acting assistant surgeon in the army, died at Santiago on September 9th, of yellow fever.—Dr. James E. H. Nichols, of New York, died in North Carolina on September 10th, of pulmonary tuberculosis. He was forty-one years of age, and was a graduate of the College of Physicians and Surgeons in the class of 1885. He was a member of many medical societies and was an attending surgeon in the throat department of the Manhattan Eye and Ear Hospital. He went South about a year ago on account of his health, which had been failing for some time.

The American Microscopical Society.—The twenty-first annual meeting of this society was held in Syracuse, N. Y., August 30 to September 1, 1898, under the presidency of Dr. V. A. Moore. The following officers were elected to serve during the ensuing year: *President*, Dr. William C. Krauss, of Buffalo; *First Vice-President*, Prof. A. M. Bleile, of Columbus, Ohio; *Second Vice-President*, Dr. G. C. Huber, of Ann Arbor, Mich.; *Secretary*, Prof. Henry D. Ward, of Lincoln, Neb.; *Treasurer*, Mr. Magnus Pflaum, of Pittsburg; *Executive Committee*, Prof. S. H. Gage, of Ithaca, Dr. A. Clifford Mercer, of Syracuse, and Dr. V. A. Moore, of Ithaca.

Starvation in Russia.—Another famine is imminent in certain provinces of eastern Russia, especially in Kazan. Owing to a prolonged drought, the harvests have failed utterly and fodder for cattle has already become exceedingly scarce. There is scarcely a wisp of hay or straw, and in some parts the cattle are being fed with old material taken from the thatched roofs of the peasants' cottages. What oxen and horses cannot be sold at greatly reduced prices are dying from starvation or from sickness caused by spoiled and unsuitable fodder. There is still enough wheat for present needs, but the distress is expected to be far greater in the coming winter, when the population, already impoverished and exhausted by previous years of want and scarcity, will have little strength to bear the privation of long-continued famine.

A Fund for Women Medical Students.—According to the provisions of the will of Miss Arethusa L. Forbes, which was filed for probate in the surrogate's office in Brooklyn a few days ago, the residuary estate, after a few bequests to relatives, is left in trust with instructions "to apply the net income of all the estate which shall remain after the payment of existing debts to the payment of the tuition and instruction of meritorious young women at the Woman's Medical College of the New York Infirmary."

An Anticigarette Law.—An ordinance has been introduced in the New York City legislature providing that "any person or persons who sell or cause to be sold or given away tobacco or cigarettes, whether composed of tobacco or any other substance, to any child or minor under the age of eighteen years, within the limits of the territory embraced in the city of New York, as now constituted, shall be guilty of a misdemeanor, and upon conviction thereof shall be punishable by a fine of $10 or ten days' imprisonment, or both, within the discretion of the magistrate trying such offence." There is already in existence a State ordinance making it a misdemeanor for any one to sell or give tobacco or cigarettes to a person under the age of sixteen years.

Pictures for Hospitals.—A movement is on foot in Allegheny, Pa., to establish an association for the loaning of pictures to be hung on the walls of the hospitals, the pictures to make the tour of the hospitals and then to be returned to their owners. One of the originators of the movement has offered sixty of the pictures from his home. In a letter accompanying his offer, he said that many persons spend a part of the year out of the city, and during that time the pictures would do much good in the hospitals without in the least depriving their owners of the enjoyment of them.

Health of the Troops at Ponce.—There have been several cases of supposed yellow fever among the American troops quartered at Ponce, Porto Rico. It is not feared, however, that an epidemic of serious proportions will arise. There is an abundance of medical supplies there, and arrangements have been made to send immune surgeons and nurses to Ponce immediately, should the need for them become apparent. There is considerable sickness, chiefly diarrhœa, among the troops on the south shore of Porto Rico, about fifteen hundred men out of a total of eleven thousand being on the sick-list. The number of cases of typhoid fever is decreasing and no epidemic is apprehended.

Clinical Department.

GASTROSTOMY FOR STRICTURE OF THE ŒSOPHAGUS, WITH REPORT OF CASE.[1]

By EARL M. GILLIAM, M.D.,

SURGEON TO ST. ANTHONY'S HOSPITAL, COLUMBUS, OHIO.

FRANK D——, aged fifty-nine, widower, by occupation a laborer, residing at Canal Dover, Ohio, was admitted to St. Anthony's Hospital, October 23, 1897, for treatment of œsophageal trouble. I saw him the next morning and obtained the following history: His health had always been good up to last July, when suddenly he became unable to swallow solid food. This inability grew worse rapidly, and by the latter part of August he was compelled to subsist entirely on liquids. In ten weeks he lost nearly fifty pounds. The family history was good, there being no evidence of trauma, syphilis, or tuberculosis. On the introduction of a bougie into the œsophagus, a stricture was revealed near the juncture of the middle and lower portions of the tract. Daily introductions of the bougie having failed to accomplish the slightest improvement, an operation was suggested, to which the patient readily consented.

On the morning of October 30th gastrostomy was performed by the Sabanajew-Frank method. An incision three inches long was made along the left costal border into the peritoneal cavity. The stomach was drawn out of the opening a sufficient distance, and the abdominal cavity completely shut off from the field of operation by the introduction of interrupted silk sutures through the muscular and peritoneal coats of both the stomach and the abdominal wall. One and a half inches to the left and parallel to the first, a second incision was made, but only skin deep. The two incisions were then connected by tunnelling beneath the integument, and through this passage the tip of the gastric fold was drawn and sutured to the margin of the second opening; meanwhile the first incision was closed. Although the operation consumed but thirty minutes, the patient was greatly shocked; nevertheless applications of hot-water bags and injections of strychnine caused him to rally nicely.

The stomach was opened on the fourth day and a rubber catheter inserted, through which hot water and milk were injected. Three days later a larger tube was substituted for the catheter, and by attaching a funnel to it the patient managed to feed himself. In less than four weeks he gained twenty pounds. Six weeks after the operation he contracted a severe cold and was confined to bed three days, complaining constantly of excruciating pain in the region of the heart. On getting up for the first time he started to walk across the ward, but had taken only a few steps when he suddenly fell to the floor and expired.

A post-mortem examination was held that morning. The heart was found enlarged and covered with a material closely resembling colloid. The lungs, liver, and stomach appeared healthy. The diseased part of the œsophagus was removed for careful examination later on.

I was fortunate in obtaining two photographs of this case. The first was taken on the tenth day following the operation, and the second at the time of the post-mortem. Fig. 1 shows the cicatrix of the first incision and also the tube *in situ:* Fig. 2 clearly demonstrates the successful union between the abdominal and visceral parietes.

FIG. 1.

Dr. Upham, of this city, to whom I am greatly indebted, kindly consented to examine the specimen, and reported it to be malignant.

The lumen at the site of constriction was but one-eighth of an inch in diameter. No rupture was found.

Gastrostomy was suggested by Egeberg, of Norway, in 1837. He believed that in cancerous or cicatricial stenosis of the œsophagus there was a possibility of prolonging life and relieving suffering by establishing a gastric fistula. Nothing was done until 1849, when Sedillot, of Strasburg, performed the first operation. In 1874 Sidney Jones, of London, and Jacobi, of New York, reported the first successful cases; prior results were almost invariably fatal. Gross collected 207 cases, in which 29.47 per cent. of the subjects succumbed to the operation itself. Zesas gathered from different sources 162 cases, showing a mortality of 60 per cent. from cicatricial stenosis and of 84 per cent. from malignant growths. But few of the many methods devised for performing gastrostomy succeed in preventing leakage. This is of the greatest import; not only does the patient's comfort but also his nutrition depend upon it. The methods of Witzel and Sabanajew-Frank are best adapted to combat this disagreeable condition, but unfortunately they are very much restricted, being applicable only in cases in which the stomach walls are lax. Witzel prevents leakage by infolding a tube into the anterior wall of

[1] Read before the Ohio State Medical Society, May 6, 1898.

the stomach, thus establishing a long narrow fistula. The objectionable feature in this operation is that the viscus has to be opened at once, whereby the risk of sepsis is increased.

But must we be deterred from using the method even if the chances of infection are augmented? I answer No. In extreme exhaustion and emaciation it should be done, as the immediate introduction of food is imperative; but when conditions are more favorable for delay, the method *per se* is that of Sabanajew-Frank. In contracted stomachs this operation is proscribed: in fact, it is sometimes almost impossible to bring the viscus to the abdominal wall. No matter what method is used, great care must be exercised in order not to mistake the colon for the stomach; this error has been made by several surgeons. In case of doubt, the best plan to pursue is to search along the under surface of the left lobe of the liver; the first structure touched after leaving it must be the stomach. When the rectus muscle is reached, at the first incision the operator should guard against using the blade of the knife, and substitute its handle for separating the fibres. The object in doing this is to preserve as much contractility of the muscle fibres as possible, and allow it to act as a sphincter to the canal, thus preventing leakage.

E. J. Senn, of Chicago, has recently brought forth a new method, which consists in making a valve of the stomach wall itself. After the abdominal cavity is entered, the stomach is grasped near the greater curvature and pulled out in the form of a cone. Two puckering-strings of chromicized catgut are then placed parallel to each other two and a half inches below the apex of the cone, the sutures including the serous and muscular coats. These sutures when drawn tight form an isthmus. A portion of the gastro-colic omentum is then lifted up and a cuff is sutured over the constriction by means of silk. The stomach is fastened to the parietal wound with silk sutures, which include the upper portion of the cuff of omentum, the serous and muscular coats of the stomach, and all of the abdominal wall except the skin. The skin is closed with silkworm-gut sutures, the portion of the stomach which is to form the valve being left visible. The stomach can be opened at this time or later, as desired. The opening is made in the centre of the portion exposed, and should be one and a half inches in length. A rubber tube having been passed into the stomach, the stomach wall is now inverted, so as to form a circular valve, and the inversion is maintained by Lembert sutures. The author reports one case, in which there was not the slightest leakage. Abbe, of New York, has also performed Senn's operation, and reports that the plan is very satisfactory.

In closing, I desire to state, first, that gastrostomy must be considered a palliative and not a radical operation; secondly, the earlier we operate, the better the chances of success; thirdly, no one method will answer in all cases; the one which seems best adapted to the situation should be selected; and fourthly, great care must be exercised not to mistake the colon for the stomach.

FIG. 2.

INVERTED TYPHOID FEVER.[1]

BY M. GOLTMAN, C.M., M.D.,

SURGEON TO THE SHELBY COUNTY POOR AND INSANE ASYLUM, MEMPHIS, TENN.

ON September 25, 1897, I was called to see Arthur Z——, thirteen years of age, white. He was born and brought up in Memphis, and was bright, exceedingly energetic, and of a very nervous temperament. The mother is very nervous, has suffered a severe attack of nervous prostration (several years ago), has evidence of arthritis deformans in several of the finger-joints, and is, together with the rest of the family with one or two exceptions, subject to tonsillitis. The patient's face was flushed, and the eyes were bright; the tongue was somewhat tremulous, and was coated slightly brown in the centre, with a whitish frothy mucus along the edges. There was no splenic enlargement; the liver, heart, and lungs were normal. The appetite was poor; the bowels were constipated; the urine contained neither albumin nor sugar, was scant and high colored, with the exception of a large quantity, pale and limpid, which was passed about two hours before I saw him. The passage of this urine was preceded by a severe chill, which was followed by fever and sweating. Temperature, 104.4° F.; pulse, 132; respirations, 24.

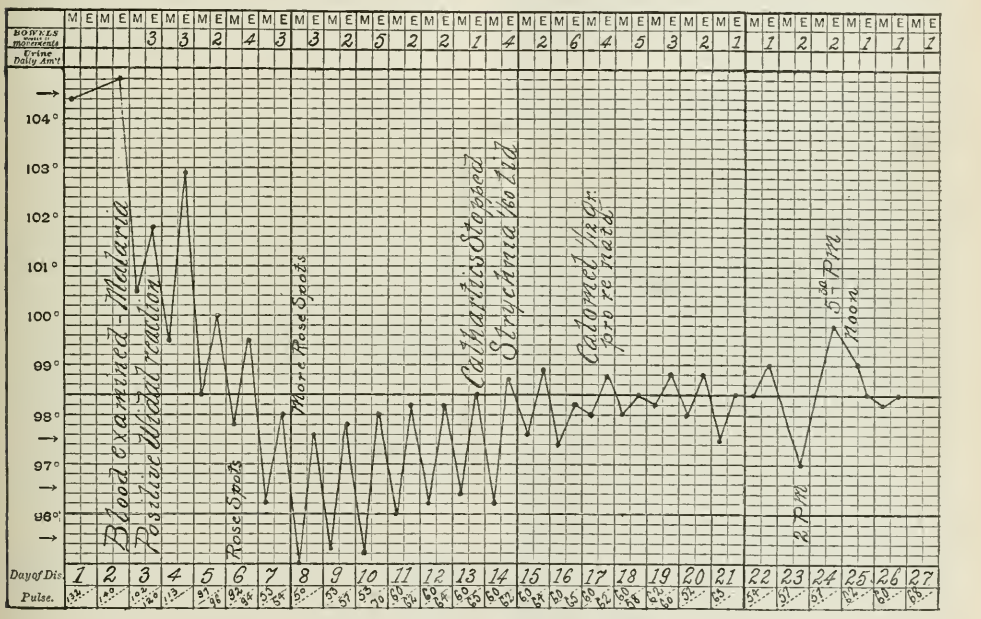
He had been indisposed, more or less, for about two weeks prior to my first visit, complaining of throbbing headaches, which were worse in the afternoon and after exercise; and there were loss of appetite, lassitude, drowsiness, disturbed sleep, constipation, and feverishness. Being an ardent cyclist, he made frequent trips far into the country in the hot sun. He recollected having partaken, on several such occasions, of both milk and water at a roadhouse where there had been sickness in the family for some time.

I diagnosed malaria, and prescribed a saline purge

[1] Read before the Memphis Medical Society, April, 1898.

and quinine in three-grain capsules very four hours, an ice cap to the head, and a cool bath. About six hours later I received word that the patient was resting nicely and was nearly, but not quite, free from fever. On September 26th he had another chill, which was of a much milder character than that of the preceding day. The quinine was continued until twenty-four grains were taken. This kept the patient comfortable, but with a temperature ranging from 99° to 101° F. until September 29th, when he had another violent chill, followed in a short time by fever of 104.8° F. On being informed of this, I made an examination of the blood for malaria. Two slides of fresh blood showed tertian organisms. Two stained specimens corroborated these findings, showing up very nicely and definitely numerous small, slightly pigmented, intracorpuscular parasites. There was no doubt about there being a malarial infection, but the persistence of slight fever for three days, the throbbing headache, anorexia, lassitude, and that "hang-dog" look, all in the face of cinchonism, were symptoms that I did not

trol experiment made on the spot proved negative. Ehrlich's diazo-reaction test proved negative, but this is not surprising, as it rarely shows before the eighth day of the disease. Outside of the slight degree of fever present, the headache, quickened pulse, and that "hang-dog look," there was nothing to indicate typhoid fever, but such was my diagnosis. As will be seen from the temperature chart, 101.5° F., after elimination of the initial malarial manifestations, was the highest point the fever reached, and this on the first and second days. After this it gradually became lower and lower, always showing a characteristic curve, however, until the morning of the 5th, when the temperature was 97.4° F. Characteristic rose spots were for the first time visible on this morning, and slight enlargement of the spleen was made out. From this day until the 13th the temperature ranged from 95° F. in the morning to 98.5° F. in the evening, and the pulse from 53 to 64 a minute. The temperature curve now gradually lessened from the 14th, and hovered between 97.8° F. and normal until the 21st. On the 22d



* Averaged about fifty ounces a day; water was given freely.

like. During the entire time (25th to the 29th) active saline cathartics, giving from two to four movements a day, were employed. Following the chill on the 29th, the administration of quinine was resumed in five-grain doses every six hours until thirty grains had been taken. This produced profound cinchonism; but in spite of it the patient continued to have slight fever until October 2d, when I saw him again. His temperature was then (9 A.M.) 100.4° F.; pulse, 102; respirations, 23. At 2:15 P.M. I made another examination of the blood, and in two unstained specimens found nothing, while three double-stained specimens showed what may have been three intracorpuscular bodies. These not accounting for the symptoms present, I procured two heavy drops of blood under the strictest antiseptic precautions, and submitted them to Dr. Krauss to be examined for typhoid. I was present when the test was made. A twenty-four-hour transplantation bouillon culture being the medium used, with the hanging-drop method typical clumping and arrest of motion took place in fifteen minutes. A control experiment made on the spot proved negative. At 2 P.M. it reached 97° F. On the 23d at 5:30 P.M. it reached 99.8° F. On the 24th at 12 M. it declined to 99° F., and after this became normal.

In a previous communication before this society I discussed the eliminative treatment of typhoid fever very extensively, and urged the adoption of the saline cathartics for the purpose of elimination in preference to anything else. I have no reason to change the opinion then expressed. They are undoubtedly best and safest. The patient may get tired of salts: then, for a day or two, calomel may be substituted in broken doses until the bowels move. A good mixture to employ is a drachm each of Epsom salts, Rochelle salts, and compound licorice syrup, repeated if necessary. Four or five movements a day are desirable. This is my main treatment; everything else is subservient to it. In advocating this treatment I fully appreciate the specific nature of typhoid fever, and while it is impossible to eliminate, *in toto*, the cause of the disease by the use of cathartics, large quantities of mixed organisms are undoubtedly forced from the intestinal

canal, which action cannot do otherwise than lessen the amount of absorption and consequent mixed intoxication. The less the intoxication, the fewer the symptoms of sepsis; and the less the sepsis, the better the chance for the patient's recovery. Elimination, to be a success, however, must begin early, before the organisms other than typhoid have gotten in their deadly work; hence early diagnosis is a *sine qua non*.

Gentlemen, we have here for analysis a case of atypical typhoid fever ushered in by the clear-cut paroxysms of a malarial infection, which was demonstrated beyond the shadow of a doubt by microscopic examination of the stained and fresh blood of the patient. More typical organisms I have never seen, and in this Dr. Krauss will bear me out. I cannot subscribe to the belief of a mixed infection—the hybrid disease, typho-malarial fever. It is, practically speaking, unknown. I am not unfamiliar with the paroxysmal fever sometimes ushering in a typhoid infection, and, being in the habit of diagnosing malaria by means of the microscope in nearly all cases, and having made such a diagnosis in this case, it was somewhat humiliating to be compelled apparently to recede from my position, and inform the anxious family that they had now to nurse a case of typhoid fever. Dr. Pheemster has, however, told me of a similar instance occurring at St. Joseph's Hospital, and the literature of the subject teems with similar cases, which, unlike my own, however, are somewhat lacking in scientific data and therefore of doubtful value. In this climate of ours, where malaria is so common, there is a proneness to consider nearly all fevers as malarial, and when they resist a calomel purge and the action of quinine for three days they are very often pronounced typhoid. It is needless to assert that in either event the liability to error is great and is increased or diminished in proportion to our laboratory knowledge, facilities, and experience. The case before you was diagnosed typhoid by the dried-blood method of Wyatt Johnston, of Montreal, in conjunction with some, if not all, of the classical symptoms; and I bring it before you for discussion for the following reasons: (1) To prove the value of early diagnosis and early elimination in the future course of the disease: (2) to prove the value of the Wyatt Johnston test as the best means of making an early diagnosis; (3) to prove that we may have an Æsculapian paradox—a fever without fever; (4) to prove that malaria may complicate typhoid fever, but only for a time, there being practically no such hybrid disease; the malarial complications may either mask the onset or disturb the convalescence; (5) to prove that much of the pathology of typhoid fever as usually taught is incorrect and not substantiated by the more modern and scientific methods of investigation; (6) to prove that by early and vigorous elimination the disease may be made to run a shorter and a milder course, in consequence, perhaps, of the lessening of the toxæmia of what is, at least in the beginning, a mixed infection.

REPORT OF A CASE OF ACUTE QUININE POISONING.[1]

By BENNETTA D. TITLOW, M.D.,

Springfield, Ohio.

A tonic containing iron, quinine, and strychnine was prescribed for Mrs. W——. There were ten grains of quinine to a four-ounce mixture, and, as the patient took only one teaspoonful dose, the poisoning was due to less than one-third of a grain of quinine. The medicine was taken after supper. In an hour Mrs. W—— complained of a burning, tingling sensation of the face, and by bedtime the sensation had spread to the entire body. I was called early the next morning, and found the patient's face badly swollen, especially the tissue about the eyes; there was an erythematous rash over the body, most marked on the face, hands, and down the spine. The patient complained of intense itching. I ordered a cooling lotion and free catharsis. In the next forty-eight hours all of the symptoms were intensified. The swelling had involved the areolar tissue about the neck, and the chain of lymphatics along the sterno-cleido-mastoid muscles. The eruption on the face was of a deep purplish color, especially across the cheeks, where a butterfly mark was really erysipelatous in appearance; that on the body was as nearly like a measles rash as anything I can describe. After trying many things without avail, I found immediate relief from a wash of dilute acetic acid. Of course I am justified in calling it a case of acute quinine poisoning only by the history of the patient, who had been poisoned in exactly the same way three times by the external use of quinine—first by a quinine and bay-rum hair wash, the next time was also by a hair wash containing quinine, and the third time by an ointment of quinine.

[1] Reported at a meeting of the Clark County, Ohio, Medical Society.

HISTORY OF A CASE OF HUNTINGTON'S CHOREA.[1]

By HARMON SMITH, M.D.,

House Physician, Kings County Hospital, Brooklyn, N. Y.

To this malady the interest of those present may be more forcibly directed, because Dr. Huntington, who has the merit of first describing lucidly this condition, and for whom it is named, was formerly a resident of Long Island (now of La Grangeville, N. Y.), and the cases he reported were from the eastern end of the island.

The important factors characterizing this disease are: 1st, its hereditary nature; 2d, the mature age, as a rule, at which it is developed; 3d, the coarse irregular movements of certain groups of muscles; 4th, the disturbance of speech: 5th, the gradual dementia which usually follows previous to death; also the immunity which a future generation enjoys if the thread of heredity is once broken. The history of this patient is as follows:

James DeB——, aged twenty-nine years, fair complexion, born in Brooklyn, married, and has two children, ages eight and six respectively, and both healthy.

Family history shows hereditary nature. Paternal grandfather and grandmother died of old age, at ninety-three and eighty-seven years respectively. Maternal grandfather died at the age of sixty-five, of heart trouble. Maternal grandmother died at the age of forty, cause unknown. Father of patient first showed choreic symptoms at the age of thirty-eight. These symptoms increased in severity until his death, aged forty-eight. No history of dementia obtainable. Mother of patient died of heart trouble at the age of thirty-eight. Patient is one of six children, and comes third in order of birth. The oldest child is now a woman of thirty-six, married, has one child; both are healthy. The next is a woman with two children, all healthy. Just younger than himself is a brother, who is now twenty-five years old, and well. Then comes a sister, who, according to the statement of the patient, developed chorea at the age of thirteen, and her condition increased in

[1] Paper read and patient presented before the Brooklyn Society for Neurology, December 30, 1897. The case was from the service, in Kings County Hospital, of Dr. William Browning, with whose consent it was presented.

severity until the age of twenty-one, when she died, having shown all the characteristic symptoms of Huntington's chorea, except the early age at which it developed.

The father had chorea some time previous to the birth of this girl, but did not have it when the patient in question was born. This gives some idea of the hereditary tendency of the disease, although only one of the previous generation and two of the present generation have developed it as yet.

The sister died childless, but in the two children of this patient we may in time be able to trace still farther this inherited tendency.

Previous personal history. At the age of eighteen he had gonorrhœa. Denies specific history and abuse of alcohol. Has used tobacco to excess, often smoking twenty-five cigars a day and several pipes of tobacco. Had scarlet fever when about sixteen years of age. Was also shot in the thigh with a pistol, the ball never having been removed. The patient also gives a history of two attacks of acute articular rheumatism occurring about ten years ago, the first attack lasting three months, the second attack two months.

History of present illness. About eighteen months ago the present trouble began by slight twitching of the fingers of the left hand, followed six months later by a similar condition of the right hand. This twitching movement extended later to the hands and muscles of the forearm. About eight months after these symptoms were first noticed, similar movements began in the toes and feet, extending to the muscles of the calves. These movements in the calves were attended by some pain, and at the same time some pain in the back was noticed. The twitching of certain groups of muscles has been more marked on the left side.

The patient's eyes wander in a restless manner; both lids twitch at alternate intervals, this being more marked on the left side. These twitchings are accompanied with an oblique nodding of the head and peculiar grimaces at times. The pupils respond to accommodation but not to light; slight inequality is apparently present. Before the trouble began the patient affirms that he was an easy talker; now speech is thick, hesitating, and sticky; the tongue apparently refuses to aid in articulating. The patient says he cannot form and pronounce his words as he should like to, or as he did formerly.

Hearing is bad in the right ear, the deafness dating from a scarlet-fever attack. Tactile sense is somewhat dulled; the man is unable to pick up small objects, or to tell if a pin is between his fingers; he is also unappreciative of the touch of a camel's-hair brush. He is frequently unable to hold light objects, and may drop cups and glasses in handling them.

Writing is not much impaired, though it is slower than formerly. The gait is uncertain and hesitating, a trouble apparently due to inco-ordination. The man staggers and sways, frequently making false steps, but never falling to the floor. Standing with eyes open and feet together is accompanied with swaying until the patient falls, and that generally backward. It is apparently impossible for him to stand with the eyes shut. The memory up to the time of the first symptoms was very good, but now it is exceedingly defective.

Upon testing the muscular sense I found the patient unable to appreciate differences of one ounce, but above this he could distinguish fairly well. (An average person with the same tests can easily distinguish the difference of only half an ounce.) The temperature sense was unimpaired. The tendon reflexes were normal. The patella reflexes were slightly increased. Cutaneous reflexes were present. Hyperæmic appearance of skin over thorax and upper extremities, and patient complains of sense of formication over same area occasionally.

There was nothing abnormal in the heart sounds. Pulse, 96; quality good. Blood-vessels in good condition. The respiratory system was apparently normal. The appetite was fair, but digestion was slightly impaired. The patient suffered from nausea at times. Urinary analysis shows a specific gravity of 1.012; normal in other respects.

Pathology. Several varying conditions have been found present in the few cases brought to autopsy, but so indefinite are the conclusions that it may be said that the pathology is generally considered unknown. Some very recent work, however, shows a close parallelism in the pathological anatomy of this disease and that of progressive dementia.

The diagnosis can be made usually upon the hereditary history, age (thirty to forty), coarse irregular movements, sticky hesitating speech, and gradual loss of mental activity.

The prognosis is unfavorable, as the patient usually goes on to dementia, or dies after a progress of eight to ten years of the disease.

A CASE OF SUPERNUMERARY ARTERY OF THE OPTIC DISC PROJECTING INTO THE VITREOUS HUMOR.

By J. HERBERT CLAIBORNE, Jr., M.D.,
NEW YORK.

A YOUNG colored woman, twenty-five years of age, presented herself at the New Amsterdam Eye and Ear Hospital on account of a frontal headache. A slight compound hyperopic error was found, the correction of which relieved her symptoms.

On looking into the eyes, there was found a curious formation of the retinal arteries. A glance at the figure below will give a clear idea of the phenomenon in each eye. In the right eye a supernumerary artery emerges from the upper and inner edge of the disc, runs forward into the vitreous, turns sharply upon itself, and, after pursuing a meandering course returns almost to the level of the disc, whence it is distributed to the retina in a normal manner. In the left eye the erring artery arises from the inner side of the disc just within its boundary, and, plunging forward into the vitreous, turns upon itself, making three loops, and finally is distributed to the retina from a point very near its origin. The artery in each eye was filled with blood, but in the left eye it was larger and more nearly bore the dignity of a central artery. On the right side it was smaller, and had, in fact, a rudimentary look; nevertheless it was filled with blood throughout. To my eye both arteries projected more nearly in a straight line than is indicated by the drawings, so that the foreshortening seemed greater.

I saw the apex of the loop in the right eye with + 4 D, and that of the loop in the left eye with + 3 D. I believe, however, that they projected farther forward than that measurement would indicate.

At the first blush the idea that these arteries were modifications of the fœtal central artery of the vitreous humor presented itself. More careful reflection, however, convinced me of the incorrectness of this view. They are beyond question supernumerary central arteries.

The first view that I entertained led me into a study of the literature of the remnants of the hyaloid artery. The cases of this condition that have been reported are so numerous that it would be neither profitable nor pertinent to review them. David de Beck, in a monograph published by Robert Clarke & Co., Cincinnati, Ohio, 1890, has thoroughly reviewed the subject of persistent hyaloid artery, and has collected

cases illustrating all the modifications of this phenomenon. He divides them into twelve groups. In his eighth division, "strand containing blood," he places twelve cases, to which the following are the references:

1. Liebreich: Trans. Path. Soc., London, 1871.
2. Little: Transactions Amer. Oph. Soc. (17th), 1875.
3. Schapringer: Arch. Oph. and Otol., iii., 1873.
4. Czernak: Centralbl. für Augenh., vii., 1883.
5. Reibau: Charité Annalen, i., 1876.
6. Fournet: Recueil d'Ophthal., ii., 1880.
7. Hirselberg: Centralblatt für Augenh., 5, 7, 9, 1881, 3–5.
8. Callan: Two cases, New York Med. Jour., xxii., 1875.
9. Kip: Arch. of Oph. and Otol., vol. iii., p. 70, 1873.
10. Szili: Centralblatt für Augenh., ix., 1885.
11. Hunike: Am. Jour. Oph., ii., 1885.
12. Frost: Trans. Oph. Soc. United Kingdom, vii., 1887, and a number of others.
13. Moll, later case: Hirschberg's Centralblatt für pr. Augenh., p. 75, 1896.

Referring to these cases, he says: "There is quite a group of cases that have usually been included under the head of persistent hyaloid vessels, which, if included here, would swell this group to very considerable proportions. These are the cases where a vessel containing blood emerges from the disc, passes a

A. B.

Upright Image. An artery emerging from each disc extends in a spiral loop forward into the vitreous, and re-entering the disc passes out into the retina. *A*, right; *B*, left.

greater or less distance into the vitreous, and then turns upon itself to pass back again to the disc or retina. It either disappears in the disc or is distributed to the retina. It is manifestly erroneous to include these cases under the head of persistent hyaloid vessels. They have no genetic claim here. Only the most superficial consideration, misled by position alone, can regard them as belonging to the class of persistent hyaloid artery."

This monograph can be found among "American Ophthalmological Monographs," No. 1, vol. iii., 1890.

The views expressed above so fully set forth my own that I have transcribed them bodily. The condition in Liebreich's case, No. 1 cited above, bears considerable likeness to the right eye of my patient. That in Little's, No. 2, is very similar to the left eye of my patient. Schapringer's likewise resembles the latter. All these observers expressed the view that the formation was a modification of the persistent hyaloid artery. In a personal communication to me, Dr. Schapringer has expressed a doubt as to the correctness of his former views.

It seems to me high time that we should no longer swell the literature of persistent hyaloid artery by reporting these cases under that head. It seems to me they should be grouped under this head: Supernumerary arteries of the optic disc.

I wish to express my indebtedness to Dr. Ward A. Holden, who has made the drawing for me; and to Dr. A. Schapringer, who has furnished me with references to the literature of the subject.

29 West Thirty-Sixth Street.

HYDRAMNIOS AND TWIN PREGNANCY.[1]

By J. T. JOSEPH BIRD, M.D.,

NEW YORK.

The condition of hydramnios is of such infrequent occurrence that this fact must be my only excuse for reporting this case. Mrs. W. P—— consulted me on November 2, 1897, with reference to her approaching confinement, and gave the following history: She is thirty-three years of age, married eight years, and has given birth to three children, two of whom are now living, one having died of pneumonia at two and one-half years. Since her tenth year of age she has had several attacks of rheumatic fever of sufficient severity to confine her to bed on each occasion. Following her first attack of rheumatism she had chorea. The patient has never enjoyed vigorous health, though this has improved since her marriage.

Shortness of breath on slight exercise has been noticed of late. There is no history of syphilis or alcoholism. There has always been some dysmenorrhœa. The last regular menstruation occurred six months ago, May 20th, though there has been a very slight flow for two or to three hours at each recurrent period since that date.

Noting an excessively large abdomen for a six months' pregnancy, I asked for an immediate examination, with the following result: The breasts are enlarged and give colostrum. The abdomen is dome-shaped, evenly enlarged, and offers a symmetrical tumor extending from the pubes to the ensiform cartilage; the umbilicus is slightly protuberant, lineæ albicantes are present, there is some pigmentation, and the superficial abdominal veins are prominent. The tumor is elastic on palpation, and gives a well-marked fluctuation wave noticeable in all directions through the abdomen. No fœtus is discernible, no fœtal heart sounds are heard, nothing like a uterine tumor can be mapped out.

The vaginal veins are enlarged, the membrane is very blue, the cervix soft, and examination for ballottement is negative. Both legs are œdematous, the left more so than the right. The veins of both extremities are enlarged, those of the right side being more noticeably so. In the sitting posture the abdominal enlargement extends to within an inch of the ensiform cartilage. The heart examination gives aortic stenosis and mitral insufficiency.

With this history and these physical signs present, the interesting question is, What is the diagnosis? Of the question of pregnancy there can be little doubt, for we have a history of amenorrhœa for six months, mammary changes and darkened areolæ, marked blueness of the vagina with distended veins, and marked softening of the cervix, though no uterine tumor can be felt, no fœtal heart sounds are heard, and no ballottement is present. Then what is the attending complication? Is it an ovarian tumor, hydramnios, ascites, or a distended uterus?

As regards an ovarian cyst, the patient did not notice any lateral enlargement of the abdomen previ-

[1] Reported at a meeting of the Harlem Medical Society, May 9, 1898.

ous to the suspension of menstruation, and the growth enlarged more rapidly and uniformly than an ovarian tumor commonly does. Besides this, we have a tumor of the same consistence throughout the abdomen, and no sulcus to suggest the presence of two growths. The percussion wave, also, extends in all directions through the abdomen, and is not limited, as we should expect to find it, in a cyst of the ovary.

A uterus distended with fluid enlarges slowly, and gives none of the positive signs of pregnancy.

Hydramnios. In favor of this condition we had a large elastic tumor, but no recognizable uterine walls, no fœtal mobility, and fluctuation was very well marked.

Ascites. The symmetrical enlargement of the abdomen, the wave of fluctuation well marked in all directions throughout the abdomen, the umbilical protuberance and prominent abdominal veins, all made this the most likely complication, though there was no manifest cause for that condition in the liver; and while the patient had an endocarditis, there were not the general œdema and albuminuria that accompany ascites of cardiac or renal origin. This opinion was concurred in by a well-known gynæcologist and by a general practitioner, an honorable member of this society.

Acting on this diagnosis, I did a paracentesis, following the method and antiseptic precautions usual in such cases. The fluid first withdrawn was clear and quite transparent, and was followed by a flow of fluid blood that continued for an instant only and then suddenly ceased. A catheter was passed through the cannula and a small quantity of bloody fluid withdrawn. In all a pint of fluid was obtained and the size of the abdomen was reduced from forty to thirty-nine inches. This was not considered a satisfactory result. No untoward symptoms followed, and after four days' rest in bed, the patient was up and about feeling very well.

Ten days later premature labor came on, and the patient was delivered of two dead fœtuses. In the case of one the integument was very dark, the cord was black and much attenuated, and presented the appearance of having been constricted by that of its fellow. For two days the fundus remained as high as the umbilicus, a condition probably due to the overdistention of the uterine walls. Recovery was most satisfactory; and it is hardly necessary to add that no signs of fluid remained in the abdomen post partum.

The Consequences of Nerve Section. — Division of a nerve has for its consequences in order of time: (1) Paralysis of motion or of sensation, or of both, according as the nerve cut is motor or sensory or mixed; this paralysis is immediate and local; (2) loss of excitability of the nerve, coming on gradually and becoming complete within a few days: direct muscular excitability persisting for an indefinite time, especially to the galvanic current; (3) degeneration of the peripheral end of the nerve, also a gradual process, visible within a day or two, well marked at the end of three or four days, complete in about ten days; (4) regeneration of the previously fully degenerated peripheral end of the nerve, a still more gradual process, commencing indefinitely, but clearly visible about a month after the lesion has been produced and requiring from three to six months to complete itself, resulting in (5) restored motility, sensibility, and excitability. These statements refer to the results of experiments upon warm-blooded animals; in cold-blooded animals the last four stages are much more slowly consummated; in young warm-blooded animals, on the contrary, the processes are accomplished more rapidly.—Dr. Augustus Waller, "An Introduction to Human Physiology," page 354.

Surgical Suggestions.

Operations upon Albuminurics.—Dr. Mongour (*Le Scalpel*, June 19th) has investigated the question of operations in the presence of albuminuria. Surgeons do not agree on this question: some few declare that they pay no attention to this condition; others have fixed an arbitrary quantity of albumin (generally from five to six grams to the litre), in excess of which quantity they do not operate; again some institute a course of medical treatment and do not intervene until the albuminuria falls within the prescribed amount. Dr. Mongour divides this class of patients into three categories: (1) Albuminuria, constituting the only symptom of renal lesion, is no contraindication for operations. (2) Albuminuria, whatever may be the quantity, coexisting with signs of Bright's disease (auditory and visual troubles, vertigo, etc.), is a formal indication for reducing to a minimum the work of the kidneys by prescribing a milk diet. If under this treatment functional signs disappear, any intervention is legitimate. If, on the other hand, there is no improvement, we should abstain from all operative interference unless immediate death threatens. (3) Albuminuria, whatever may be the quantity, existing in conjunction with marked signs of renal insufficiency (œdema, ascites, etc.), if coming on in the course of a subacute nephritis, precludes operation until after treatment has been undergone. If the results are favorable intervention is legitimate, otherwise no operation should be undertaken, unless it is a question of life or death. In this category of patients the author makes one reservation: cases in which nephritis is accompanied by all the classical signs of Bright's disease, which seem to be daily aggravated by a suppurative lesion.

Celluloid Bandages.—Dr. Walravens has reported his experience with these bandages (*Le Scalpel*, June 19th), which possess the advantage of being very light. A celluloid corset weighs three hundred grams, while one of plaster weighs two kilograms three hundred grams. The solidity and rigidity of celluloid are at least equal to those of plaster. It is impermeable to perspiration, urine, or pus, while these excretions macerate plaster. It is elastic, and as it neither breaks nor cracks it permits of massage. Used with steel articulations or with celluloid itself, it is superior to even the most complicated bandages. As celluloid is softened by a moderate degree of heat, the form can be corrected if necessary. The only serious inconvenience of celluloid is that it does not harden so quickly as plaster, requiring two or three hours. Dr. Walravens thinks its inflammability has been exaggerated, and that in this respect celluloid is no more dangerous than clothing. As it is impermeable, openings should be left here and there for the evaporation of the perspiration. As celluloid solidifies so slowly, it is necessary to use a mould. Make a solution of one part celluloid to three parts acetone in a vessel with a large opening, and stir from time to time. The more readily the acetone evaporates the more homogeneous will be the solution. It should be sufficiently liquid to thread when dropped from the spatula. If too dense it is difficult to spread. The surgeon should wear gloves or else anoint the hands with vaseline. Dr. Walraven completes his dressing as follows: After steeping the bandages in acetone he places them in a solution of celluloid, which easily penetrates. He then rolls them on the mould, adds one or two layers of celluloid and allows it to dry. If it is not sufficiently thick when dry, as many more layers as are necessary may be added. One may place a jersey on the mould and apply acetone and then celluloid and allow it to dry; if necessary this process may be repeated.

Radical Cure of Umbilical Hernia.—Dr. Focas, in an article on this subject (*Archives Provinciales de Chirurgie*, July 1st), advises the following method of procedure, for which he does not claim any novelty, but holds that there is an advantage in working from behind forward; that is, from the peritoneum toward the skin, cutting at one time all that is to be cut and reducing by traction all that should remain. He divides this operation into two steps: "First, make a small medial classical laparotomy in the healthy wall of the abdomen, between the hernia and the xiphoid appendix. We thus make a peritoneal opening just sufficient to admit the left index finger, which explores the neck of the sac. This exploration will show the nature of the organs penetrating the hernia, whether epiploon or intestines. Without removing the finger incline it to the left outside the sac and on the finger, acting as a cannula sound, open the abdominal wall with a pair of scissors, following a curved line with the concavity inward. Compresses protect the abdominal cavity already opened. The finger after again reaching the neck explores the right side of the sac to its limit and the wall is incised from this side, following a curved line symmetrical with the first. The umbilical region (skin, umbilicus, sac, and hernia) then forms a flap with the pedicle below. This flap can be turned back so as to expose the peritoneal space with the umbilical ring, giving passage to the omentum or the intestines. The motion of this flap is sufficient by the attraction it gives to the contents of the sac to reduce all that can be reduced—that is, all that is not adherent or strangulated. Any epiploic portion which has not been reduced by this method is adherent to the sac and must be removed. It suffices to cut the epiploic cord after ligating and to cut the inferior pedicle of the flap. Every intestinal portion that has not been reduced in the same way must be reinstated, and to do this it suffices to force the intestine back through the neck of the sac. After the contents of the sac have been disposed of, the entire flap is cut away, the peritoneal cavity being protected by aseptic compresses. Second, divide the walls, isolate the peritoneum to find under it in uncovering the right muscles that we do not easily find in working from the front backward. Take the edges and proceed to suture in three layers. Have recourse to Quenue's method if it is appropriate."

Peritonitis.—In the early stages, when operative interference is advisable and not without hope, the symptoms may be grouped as follows: (1) Pain general, becoming local, or local, becoming general; (2) tenderness, general, becoming local, or local, becoming general; (3) rigidity of the abdominal muscles; (4) vomiting, green; (5) rise of pulse and temperature; (6) shock, varying in depth; (7) diminished peristalsis. In fully developed peritonitis, in which the wisdom of interference is questionable, the symptoms are: (1) Pain lessened or absent; (2) tenderness general; (3) distention excessive, replacing rigidity; (4) vomiting excessive, dark or fæcal; (5) obstipation, peristaltic movement not heard; (6) rapid and feeble pulse; (7) high or low temperature; (8) lividity of abdominal skin, cold extremities; (9) peritoneal facies; (10) mind clear. In hopeless cases the above symptoms are increased with collapse; the patient is moribund.—Drs. Richardson and Cobb, "Parke's System of Surgery," p. 386, vol. ii.

Vaginal Cocci.—All seem to me agreed that the streptococci and staphylococci which are found in the vagina by no means have their normal virulence, but that favorable conditions increase their virulence.—Veit.

A Consideration of the Urinary Distance as a Diagnostic Factor of Prostatic Hypertrophy.—(1) The urinary distance varies in the adult healthy male from something over six inches to something under ten inches, but may be averaged at eight inches. (2) The shorter lengths are found in short individuals having a small penis. A large organ naturally contains a long urethra, and this is most certainly the case if the individual be tall. (3) The age of the individual seems to cause a very moderate increase in the urethral length, irrespective of disease. (4) In prostatic hypertrophy the urinary distance averages more than eight inches, and is longer in cases of peripheral general hypertrophy than when the enlargement is median or in cases of bar. (5) In a doubtful case, a consideration of the urinary distance may become an important element in the diagnosis.—Dr. E. L. Keyes, *Journal of Cutaneous and Genito-Urinary Diseases*, August.

Are Complete Castrates Capable of Procreation?—(1) In animals, for a varying period after complete castration, normal spermatozoa are found in the contents of the seminal vesicles. (2) This period varies in different animals, being six days for the dog, seven days for the cat, and fourteen for the guinea-pig. (3) In man, clinical cases are recorded in which fecundation of the female has occurred after coitus with a male who had been completely castrated, but in accepting the correctness of such statements we must remember the adage that "accidents may happen in the best regulated families." Still, Princeteau's case (if correct) proves that spermatozoa do exist for a certain time in the seminal vesicles of a eunuch, and, arguing from analogy of what occurs in animals, this is quite probable. (4) Still pursuing the analogy in man, as in the dog and cat, a complete castrate may be capable of procreation, providing the coitus occurs within the first seven days after the castration.—Dr. Frederick R. Sturgis, *Journal of Cutaneous and Genito-Urinary Diseases*, August.

Urethral Fever.—Tying a catheter into the urethra is one of the most effectual methods of preventing the occurrence of rigors, a fact that is quite inexplicable if rigors are caused by reflex irritation of the deep part of the urethra.—Moullin.

The Treatment of Hemorrhoids.—Dr. Coston (*Medical and Surgical Reporter*) gives these points in favor of the clamp and cautery: 1. In the operation with the ligature you tie up the most sensitive of all nerve ends, and there is intense pain, which will be kept up until the stump sloughs and the ligature comes off. In the cautery operation the nerve end is simply cut away and cauterized, and there is nothing left for it to do but cicatrize, and it is left in the very best possible condition for this. 2. The ligature may slip off and secondary hemorrhage occur; after the clamp-and-cautery operation there is no danger of secondary hemorrhage. If hemorrhage occurs, it does so immediately, and the operator can blame only himself for it. 3. There is no danger of a recurrence. Kelsey, of New York, and Smith, of London, who have a large experience with operations, support this statement. It will be admitted that recurrences do follow the ligature operation. 4. Convalescence is much more quickly completed, for the reason that it begins at once under the eschar produced by the cautery, and would be completed by the time the ligature came away should the two operations be used on separate tumors in the same case. 5. The mortality following the clamp-and-cautery operation is practically *nil*. 6. The clamp-and-cautery operation requires less after-care from the operation. 7. There are no unpleasant sequelæ.

The Treatment of Penetrating Wounds of the Abdomen.—Vulliet (*Revue Médicale de la Suisse Romande*, after an analysis of three hundred and fifty-five cases, seventy-seven of which were treated on the expectant plan and two hundred and fifty-eight by laparotomy, draws the following conclusions: 1. To establish the fact of penetration the wound must be enlarged, probing being insufficient. Exploratory laparotomy must be performed at once in case of perforation. 2. It is often impossible to decide from the symptoms whether the intestine is perforated or not; symptoms of peritonitis often accompany slight cases, while they may be absent in multiple perforations. 3. Sure signs of perforation of the intestine, as fistula or evacuation of a bullet per rectum, are very exceptional. 4. Exploratory laparotomy is without danger. 5. Both statistics and experiments show that spontaneous healing of intestinal perforations without septic peritonitis is rare. 6. Early operation aids in the prevention of peritonitis, which, when once established, nearly always ends fatally. 7. Even when death does occur, it need not be attributed to a long and difficult operation; it may have been due to the gravity of the lesions. Operation has certainly saved many who otherwise would have died. 8. If there are no abdominal symptoms present forty-eight hours after the infliction of the wound, perforation of the intestine can be excluded almost with certainty; if there are signs of peritonitis, abdominal section and washing out give the only remaining chance for recovery. Deaths in the latter case are due to the expectant treatment and not to the operation. 9. Shock is no contraindication to operation; it is often caused by severe hemorrhage, and the fear that the patient may die on the table must not preclude an operation which has saved life. In these cases stimulants and intravenous saline injections should be given freely. 10. The incision should be median and long in the majority of cases, as this facilitates exploration. The cavity should be washed out and drained. 11. The above conclusions apply only in civil life, when it is possible to use all aseptic precautions; in war the question of operation *versus* expectant treatment must be considered as still unsettled.

Vaginal Hysterectomy.—We may say that practically vaginal hysterectomy has no mortality, and abdominal to-day gives us quite the same guarantee. But we are convinced that the mode of operating is of no consequence in cancer. It may finally be said that, wherever cancer is situated, after extirpation relapse is inevitable in the present state of our knowledge of its therapy, and radical cure to-day is the "exception." Operation, as it stops hemorrhage, relieves pain, and suppresses the ichorous discharge, should not be refused the patient. Cancer of the uterus, however treated, is progressively fatal, although, everything considered, hysterectomy is perhaps among the best of palliative remedies.—Dr. Jacobs, *Gazette de Gynécologie.*

Thyrotomy for Tuberculosis of the Larynx.—Dr. Castex (*Le Scalpel*, January 1, 1898) some years ago proposed an operation for the purpose of arresting the progress of phthisis of the larynx; this is thyrotomy. Dr. Goris, of Brussels, has performed some operations of this kind. He opens the larynx, curettes the tubercles, and cauterizes them with the thermocautery. After this he closes the larynx. He thinks that thyrotomy is an operation which involves little danger and admits of bettering the condition when the two parts of the larynx are much retracted. The voice returns soon after the operation and the consecutive dysphasia does not last more than a few days.

Gunshot Wounds.—(1) In theory and practice military surgery is equivalent in every respect to emergency practice in civil life. (2) The wounded soldier is entitled to the same degree of immunity against infection as are persons in civil life suffering from similar injuries. (3) The fate of the wounded rests in the hands of the one who applies the first dressing. (4) The first dressing should be as simple as possible, including an antiseptic powder (composed of boric acid, four parts; salicylic acid, one part), a small compress of cotton, safety pins, and a piece of gauze forty inches square. (5) Any attempt to disinfect a wound on the battlefield is impracticable. (6) The first-dressing stations and the field hospitals are the legitimate places where the work of the hospital corps and company bearers is to be revised and supplemented. All formal operations must be performed in the field hospitals, where the wounded can receive the full benefits of aseptic and antiseptic precautions. (7) Probing for bullets on the battlefield must be absolutely prohibited. (8) Elastic constriction for the arrest of hemorrhage must not be continued for more than four or six hours, for fear of causing gangrene. (9) The *x*-ray will prove a more valuable diagnostic resource than the probe in locating bullets lodged in the body. (10) Gunshot wounds of the extremities must be treated upon the most conservative plan, the indications for primary amputation being limited to cases in which injury of the soft parts, vessels, and nerves suspends or seriously threatens the nutrition of the limb below the seat of injury. (11) Operative interference is indicated in all penetrating gunshot wounds of the skull. (12) Gunshot wounds of the chest should be treated by hermetically sealing the wounds under the strictest aseptic precautions. (13) Laparotomy in penetrating gunshot wounds of the abdomen is indicated in all cases in which life is threatened by hemorrhage of visceral wounds and the general condition of the patient is such as to sustain the expectation that he will survive the immediate effects of the operation.—Dr. Nicholas Senn, *Journal of the American Medical Association*, July 9th.

Cancrum Oris.—This is now fortunately a rarely seen form of gangrene. In its treatment fuming nitric acid was found superior to carbolic from the outset.—MacMasters, *Australasian Medical Gazette.*

Fracture of the Inferior Maxilla.—Dr. Moriarty (*Boston Medical and Surgical Journal*) makes impressions of both jaws, the fracture being unreduced; then plaster casts, indicating the line of fracture, which is cut through with a fine saw, are made. The deformity is then corrected, and a vulcanite splint, from each side of which a wire projects, is made; these wires are joined behind the head by a bandage. The jaws are fitted to a splint and a bandage connecting the side wires is run under the chin to support the jaw. When greater pressure is desired, a metal chin piece, fastened to the side wires by screws, may be utilized. If the symphysis be the seat of fracture, a continuous cap of gold or aluminium may be cemented to the lower central teeth.

Indications for Venesection.—1. In affections of the central nervous system, such as cerebral hyperæmia, apoplexia cerebri, inflammation of the cerebral membranes. 2. Kidney diseases in the stage of œdema and uræmia (Saccharjin and Hoffmann). 3. Cardiac disease of valvular origin. In great disturbances of circulation in which the venous system is overtaxed and the arterial pressure raised (Liebermeister). 4. In pneumonias with an exceptionally severe onset, absolutely in the first stage. 5. In various stages of chlorosis (Dyes, Wilhelmj). — Dr. Moritz Kácser, *Wiener klinische Rundschau.*

Abscess of the Liver.—Medical treatment of liver abscess is only palliative. When rupture has occurred in any direction, as long as the abscess is properly or satisfactorily evacuated, interference is not advisable. Should the evacuation be unsatisfactory, resulting in hectic fever, emaciation, and generally bad progress, a counteropening through the side should be attempted. The trocar or aspirating needle is very valuable, it may be said indispensable, in diagnosis, but comparatively useless in treatment. The best results ever obtained have been those that followed free evacuation with the knife. When pus has been located by needle or otherwise, the knife should be boldly and freely used. There is little to be gained and possibly much to lose by waiting for nature by inflammation to form protecting adhesions. The point of election is the most dependent part of the collection, or the point showing a tendency to rupture. In absence of this the points of election are just below the ribs, or in the seventh intercostal space in midaxillary line. In early operations, or before adhesions have formed, it is advisable to open the peritoneal cavity first, and pack it off by gauze preliminary to opening the abscess. The subsequent management is similar to that of abscesses in general. —*Toledo Medical and Surgical Reporter.*

The Treatment of Fractures.—1. Unless a fragment is threatening to break through the skin, the fracture should never be reduced except by a physician, and then only when apparatus is at hand to keep the parts in permanent apposition. 2. Men carrying an injured person should not keep step, as the jar to the wounded part is much greater. 3. Strychnine for shock, morphine for pain, but no alcohol. 4. Always give anæsthetics for reduction of a simple fracture. It is better and easier to reduce and set compound fractures without anæsthesia. 5. It is very rarely necessary to make a patient go through the double agony of temporary and permanent setting of the broken bones. 6. In simple fracture gentle rubbing of the ends will assist in getting rid of shreds of tissue which invariably are caught there. 7. Nowadays a surgeon will rarely be satisfied that a bone is properly set, until he has verified by the *x*-rays. 8. Plastic splints, preferably plaster of Paris, are surely the best apparatus when they can be applied. 9. Ambulant treatment is coming more into vogue. No simple fractures require constant confinement to bed, except of the innominata and upper third of the femur. 10. It is not necessary and sometimes is very harmful to wait for swelling to disappear before a permanent dressing is put on. 11. A well-applied splint with good apposition of fragments should not be removed too early. It is not necessary to apply massage early in ordinary cases. 12. Proper time for massage is two or three weeks after fracture of upper extremities, and four or five weeks for lower extremities—if the bones are slow to unite firmly.—W. L. Estes, *International Journal of Surgery.*

Some Clinical and Pathological Phases of Gall Stones.—(1) Cholelithiasis is of frequent occurrence and usually gives rise to symptoms either severe or obscure. (2) Cholesterin as a gall-stone-producing agent must be present in an abnormal quantity. (3) Cholesterin is in a great measure a product resulting from the destruction and disintegration of the epithelium of the biliary ducts and gall bladder. (4) Bilirubin-calcium, an insoluble compound formed by the union of bilirubin and the lime salts, forms the nucleus of most of the stones formed in the gall bladder. (5) Jaundice, ptomain poisoning, and suppuration are late symptoms of cholelithiasis. (6) Dyspeptic symptoms, swarthy skin, uneasiness in the region of the gall bladder (congestion of liver), and loss of weight are some of the remote and local symptoms of the presence of gall-stones. (7) Inflammatory diseases of the duodenum and bile passages are the most direct causative factors in the production of gall stones. (8) The surgery of these cases is especially difficult and the inexperienced should not undertake it. (9) A ball-valve stone usually continues to give rise to symptoms until removed by surgical means. (10) Stones in the gall bladder, producing septic symptoms, should be removed.—Dr. A. H. Cordier, *Journal of the American Medical Association*, July 9th.

Tuberculous Infection.—Antecedent inflammatory affections and trauma are the etiologic conditions that most frequently determine tuberculous infection. —Senn.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HEAT-WAVE PASSING—THE PRINCE'S CASE—EPIDEMIC AT BELFAST—MAIDSTONE HEALTHY—THE CONGRESS OF PUBLIC HEALTH—SIR CHARLES CAMERON'S ADDRESS—VACCINATION OR VACILLATION ACT—A JOURNAL OF TROPICAL MEDICINE.

London, August 12, 1898.

The heat wave continued into the present week and caused considerable distress and disease. There was an appreciable diminution of the temperature on Tuesday, and fewer applications for admission to the hospitals were made. The thermometer, in fact, showed a fall of twelve degrees, it marking only 77° F. in the shade, though in many localities the fall was less. With variations since there has been a decided decrease in sudden attacks and in fatalities, but other summer diseases are very numerous and keep the profession busy, and will, no doubt, affect the death rate later. The lower temperature has been generally marked and to-day there is a further fall.

The Prince of Wales has made steady progress and the surgeons in attendance are quite satisfied with his condition. There are but slight effusion in the joint and not much swelling in the surrounding tissues. The separation between the fragments of the patella does not exceed a quarter of an inch. Some passive movements of the joint have been made without giving rise to any pain or inconvenience. Of course the upper fragment has been carefully controlled on these occasions. Gentle massage has been for some time used to the muscles. In another two or three weeks it is hoped that a check splint will be employed, by the aid of which the patient may venture on crutches. The Prince has had some pleasant trips on his yacht, and a longer cruise is projected for him, when it is hoped he may be carried ashore at some of the towns and have carriage exercise.

Belfast is suffering from a serious epidemic of typhoid fever. Last week 257 new cases were notified, making a total of 605 cases during the first three weeks of August. At the weekly meeting of the poor law board on Tuesday, Dr. Biggar reported that the epidemic was rapidly increasing. More than 100 cases had been admitted to the workhouse since the previous Tuesday, and additional accommodation and

more nurses were urgently needed. The fever hospital was also overcrowded; 22 cases had been admitted on the previous evening and a larger number might be expected that night. There were 300 cases in the Workhouse Hospital, and some of the nurses had broken down under the pressure of the extra work.

The board decided to engage twelve extra nurses and two doctors.

A special meeting of the public health committee of the dispensary medical officers was held in the afternoon, to consider what steps should be taken to deal with the epidemic. It was decided to have a bacteriological investigation, with a view of tracing the origin of the epidemic and determining the best method of suppressing it. In the mean time the inhabitants are being warned to consume no milk or water until after it has been boiled.

There have been rumors of another outbreak at Maidstone, but they appear to be unfounded, for at the meeting of the town council the medical officer reported that during the first three weeks of this year, during which the great epidemic came to an end, there were fourteen cases, but during the subsequent twenty-five weeks there had been only five cases, and of these three had been in all probability imported.

On Saturday the lord lieutenant of Ireland attended a dinner to the executive committee of the Health Congress at the Royal College of Physicians in Dublin. Sir C. Cameron presided, and, in proposing the usual loyal toast, alluded to the accident to the Prince of Wales. In replying, the lord lieutenant expressed his pleasure at the progress made in sanitary science in Ireland, and especially in Dublin, where he found the drainage system and the housing of the working-classes greatly improved.

This congress was promoted by the Royal Institute of Public Health, and attracted a large number of visitors to Dublin. It extended from the 19th to the 23d inst.

The presidential address by Sir Charles A. Cameron dealt in a masterly manner with topics of general and local interest in regard to public health. Thus, after considering the causes of the high urban death rate and the encouragement afforded by the improving sanitary state of towns, as seen in the results that have already accrued, he went on to show that the increase in the English urban population has not caused an increased death rate. In fact, the increased density of population, though unfavorable to health, has not sufficed to counteract the good effects of improved public and private hygiene. London has doubled its population since 1851, and Sir Charles said it was truly wonderful that its vast population should in 1897 have had so low a death rate as 17.7 per 1,000.

That the health of English towns continues to improve is clearly proved by statistics, from which Sir Charles found that in the period 1851 to 1870 the deaths in towns were twenty-five per cent. greater than the deaths in the country for equal numbers of people; but in the period 1871 to 1896 the excess was reduced to 13.5 per cent., or nearly one-half. Here he remarked, *en passant*, that the rate was lower among females than males, and as an encouragement to intending benedicts told them that the duration of life was greater among married men than among celibates. No doubt, he said, the former were taken better care of.

Sir Charles then proceeded to describe at considerable length the state of public health in Dublin, where the congress he was addressing was assembled. He showed what had been done, what remained to be done, and urged that sanitary efforts might not be relaxed. He observed that the "good old times" so often commended were by no means happier than these, but rather the reverse. "Leprosy and malarial fevers," he said, "have vanished from these countries. Typhus fever, which once filled the wards of the Dublin fever hospitals with patients, is now rarely met with. Fifty years ago people disfigured by small-pox might be seen in every street; now that loathsome disease is disappearing under the influence of vaccination and the improved hygienic condition of towns and people.

"In this connection I must express my satisfaction that vaccination is still compulsory in Ireland, although no longer so in England. I believe that the medical profession is practically unanimous in regretting that the vaccination act, just passed, permits in England and Wales the so-called 'conscientious objector' to refuse to have his child vaccinated. In Ireland, if vaccination is sometimes neglected, it is not from want of belief in its efficacy or contempt of the law."

With reference to this it should be observed that throughout the congress the same view was held by every speaker who had occasion to allude to the subject.

In fact the new measure, which is getting the nickname of the "vacillation act," has brought much discredit on the government, and the so-called conscientious objector is becoming ridiculous, although he has put in an appearance already before the magistrates, one of whom said he had no means of satisfying himself of the objector's conscientiousness, while others have postponed the consideration of these cases.

The *Journal of Tropical Medicine* has been started, under the editorship of Mr. James Cantlie, formerly of Hong Kong, and Dr. W. J. Simpson, lately medical officer of health for Calcutta. The first number is dated August 15th, and it is proposed to issue the journal on the 15th of each month. This number contains a full report of the tropical section of the Edinburgh meeting, besides original communications, leading articles, reviews, and other material of a medical monthly. There seems to be room for such a publication, and the revived interest in tropical medicine makes its appearance timely. The subscription is 17s. a year, post free.

FLIES AS SPREADERS OF SICKNESS IN CAMPS.

To the Editor of the Medical Record.

Sir: The recent discussion of the spread of fevers and dysentery in the army has assumed the proportions of a national scandal. There is incessant talk and yet the difficulty does not abate perceptibly. There is a great outcry in reference to the necessity for pure water especially, although much is said in regard to the character of the food and the need of medical and other supplies. Under such a blaze of indignation and criticism as has flared up from one end to the other of the entire country, there is no doubt that the authorities have been stimulated to do their very best. Every effort has been made and vast sums have been expended by public and private generosity, and yet the evils complained of are mitigated only in part if at all. The hospitals remain full and the soldiers are being mustered out of service hurriedly in a sort of panic, to get them away from the centres of infection. If the war were to continue it would not be possible to secure relief in this way, except partially and incompletely by constantly changing the location of encampments, as has been done so frequently and with so much recrimination the past few months. Apparently it requires only a few weeks at most for a camp to become "stale" and all the water anywhere within reach unfit for use, and then the location must be changed absolutely and entirely, according to current ideas of such matters.

It is not to be denied that there are dangers in connection with water supply, but they are not the only or the chief ones in the case of encampments. To illustrate, the writer has seen fæcal matter in shallow trenches open to the air, with the merest apology for disinfection and only lightly covered with earth at intervals of a day or two. In sultry weather this material, fresh from the bowel and in its most dangerous condition, was covered with myriads of flies, and at a short distance there was a tent, equally open to the air, for dining and cooking. To say that the flies were busy travelling back and forth between these two places is putting it mildly. I presume that in the very case just mentioned, a microscope would have revealed fly tracks of more or less fresh excrement across the meat and bread and sugar and in the milk pitcher and water jar; the excrement so deposited doubtless contained the colon bacillus and the typhoid bacillus, as well as other varieties less harmful. Even in a private house, not at all uncleanly, I have seen typhoid dejections emptied from a commode, and the latter thoughtlessly left standing without disinfection within a few feet of a pitcher of milk just left at the door, both the commode and the pitcher attracting the flies, which swarmed about and went from the one to the other. Is it strange that there were numerous cases of the disease in that house and others in the house next to it? I have seen a shallow old-fashioned watercloset fairly buzzing with flies on a hot day, and all around it open windows and doors leading into kitchens and pantries and dining-rooms. A single case of typhoid would start a severe local epidemic under such conditions. Indeed, such observations have been made only too frequently. In encampments it is the common thing.

To clinch the argument, and apparently leave no loophole for escape, I have made cultures of bacteria from flytracks and from the excrement of flies, and there seems to be not the slightest difficulty in so doing. Indeed, the evidence of every sort is so clear that I have about reached the conclusion that the conveyance of infection in the manner indicated is the chief factor in decimating the army. Certainly, so far as is known to the writer, nothing adequate has been said about it in current discussions. On the contrary, there have been intimations of the existence of ideas that are positively dangerous, if what has been here said is true. There is no doubt that air and sunlight kill infection if given time, but their very access gives opportunity for the flies to do serious mischief as conveyers of fresh infection wherever they put their feet. In a very few minutes they may load themselves with the dejections from a typhoid or dysenteric patient, not as yet sick enough to be in the hospital or under observation, and carry the poison so taken up into the very midst of the food and water ready for use at the next meal. There is no long, roundabout process involved. It is very plain and direct, and yet when thousands of lives are at stake in this way the danger passes unnoticed, and the consequences are disastrous and seem mysterious until attention is directed to the point; then it becomes simple enough in all conscience.

As regards the precautions to be taken, it is not necessary to enter into detail. Personally the writer has insisted that disinfecting solutions, preferably that of blue vitriol, be kept constantly in chamber utensils, so that all infection may be at once destroyed where there is typhoid or dysentery. The use of this same solution in waterclosets generally is found to be very satisfactory, destroying all smell and causing the flies to cease their visits. Other measures will readily suggest themselves. The important point is that the danger be fully and adequately recognized.

M. A. Veeder, M.D.

Lyons, N. Y.

APOMORPHINE.

To the Editor of the Medical Record.

Sir: I read with interest Dr. Van Dyke's note upon the use of apomorphine with negative results in two cases of morphine poisoning. Dr. Van Dyke gives as the reason why the apomorphine did not produce vomiting that the opium, in his opinion, had deadened the vomiting centre. I am surprised that Dr. Van Dyke should have used an emetic in these cases, as the morphine was entirely absorbed, and one cannot vomit morphine or any other poison out of the circulation. I have never had any but good results with apomorphine, either as an emetic or as an antispasmodic, and I always use it when indicated. Dr. Van Dyke says that ipecac and sulphate of zinc in warm water caused vomiting when the apomorphine failed. But when the reflexes are deadened to one emetic, surely they are to the others. Perhaps the apomorphine used in these cases had been kept on hand for some time and had lost its properties.

S. A. Visanska, M.D.

66½ Whitehall Street, Atlanta, Ga.

EARTH CLOSETS IN THE ARMY CAMPS.

To the Editor of the Medical Record.

Sir: Dr. B. T. Kneeland, formerly surgeon of the one hundred and thirtieth New York infantry, and who is still at the age of seventy in active practice at Dalton, N. Y., relates the following, which might with profit be brought to the attention of some in charge of our army camps to-day.

When located in camp at Suffolk, Va., in 1861, he asked for and was given a detail of five men from each company. These he directed each morning to cover with two inches of fresh earth the daily accumulation in the sinks. Before this various "deodorizers" had been employed, which had proven comparatively ineffective.

The colonel of the regiment, a man generally well informed and who especially prided himself on his fair knowledge of affairs pertaining to medicine and sanitation, at once missed "Uncle Sam's regulation odor," as he termed it. On making inquiry he was reminded by the doctor that one other authority on such matters should have been included in his reading, and was referred to Moses.

This practice, which afterward was generally employed in the army, Dr. Kneeland claims had its inception as above described.

Mt. Morris, N. Y.

ANÆSTHESIA AND ITS ADMINISTRATION IN GREAT BRITAIN AND IRELAND.

To the Editor of the Medical Record.

Sir: My attention has been drawn to an article which appeared in your issue of November 13th last, under the title of "Anæsthesia and its Administration in Great Britain and Ireland," by Prof. George Bell Todd, of Glasgow, and in which I am made to say that the Women's Hospital, Euston Road, London, "is remarkable for the failures in administering chloroform correctly."

The article in question was a private communication from myself to a friend, and published without my knowledge or consent.

With reference to the extract above quoted I would remark that information has been furnished to me by the authorities of the said hospital, from which it appears that between January 1, 1894, and December 31, 1897, anæsthetics were administered thirteen hundred times at the said hospital, that there were during

that period two deaths on the operating-table. Inquests were held in both cases, and in one instance only was a verdict of "death from chloroform" returned. This shows that the above-quoted statement is unfounded and incorrect, and I regret that the same should have appeared in the article referred to.

GEORGE BELL TODD, M.B.

GLASGOW, August 25, 1898.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 10, 1898:

	Cases.	Deaths.
Tuberculosis	159	172
Typhoid fever	143	49
Scarlet fever	61	4
Measles	41	5
Diphtheria	86	13
Chicken-pox	1	0
Cerebro-spinal meningitis	0	5
Laryngeal diphtheria (croup)	2	2

A Rat-Plague Bacillus.—Dr. Isatchenko, of the bacteriological laboratory attached to the agricultural department of the Russian government, has just made a preliminary communication on a new microbe pathogenic to rats, which he has discovered. A disease which assumed epidemic proportions broke out among the rats kept for experimental purposes in the laboratory, and from the liver and spleen of affected animals a bacillus was isolated which proved on inoculation to be extremely fatal as regards both rats and mice. Receiving food infected with this organism rats and mice invariably succumbed, the former after from eight to fourteen days, the latter after from four to eight days. Following Pasteur's example in the case of a bacillus similarly fatal to rabbits, attempts were made to turn this new microbe to practical account and utilize it as a living rat poison. The results so far have not been very encouraging, but further experiments are being made in this direction.—*Nature.*

Vegetables in Gout.—Some discussion has taken place of late in connection with the use of rhubarb as an article of diet in rheumatism. Little authoritative reference can be found to the subject in books on diet. The use of rhubarb in kidney troubles is certainly contraindicated, because rhubarb contains oxalate of lime, and for gouty persons it is regarded as inadvisable for a similar reason. In gout it is considered that rhubarb may tend to increase or to favor the production of uric acid. But doctors differ on spinach, which also affords oxalic acid, and tomatoes, that contain it in but small quantity, are allowed to figure in the gouty man's diet list. At a recent meeting of the Royal Medical and Chirurgical Society Dr. Luff read an interesting paper on the minerals of vegetables, with reference to gout. The general result of his investigations is that the minerals in spinach, Brussels sprouts, French beans, winter cabbage, turnip tops, turnips, and celery are all beneficial to a gouty person. Their minerals act chemically in preventing the deposition of gouty matter in the tissues, and spinach is said to occupy the foremost place in the list in respect to this action. These researches are interesting, because they lead us nearer to the reason why a vegetable diet should benefit a gouty man. In other words, science comes to explain the meaning of a practice which, dating from very early periods, was founded entirely upon empirical data.

The Loss from Typhoid Fever.—In the United States the loss through typhoid fever and other diseases whose germs are disseminated by our sewage-polluted water supplies is almost incomprehensible. It is within bounds to estimate the number of persons annually thus afflicted at three hundred thousand, of whom fifty thousand die. At the lowest legal valuation set upon human life, the enormous total of $278,000,000 is found to be the equivalent cash loss. If by improvement of the water supply the death rate could be reduced eighty-five per cent., $236,000,000 would remain for this purpose, and this amount at five per cent. annually for interest and sinking-fund charges for forty years, would justify an outlay of no less than $4,054,671,000 for water purification.—*The Sanitarian.*

The Surgical Treatment of Insanity and idiocy has gone out of fashion. Craniotomy may be practically excluded nowadays from the therapeutics of either microcephalus or hydrocephalus. Indeed, a celebrated surgeon has recently declared that the only thing in favor of the operation is the fact that a fair proportion of patients happily die in consequence. Trephining in general paralysis has been replaced by vertebral puncture with equally doubtful results. The gynæcologist, however, rushes in where the ordinary surgeon fears to tread, and Dr. Hall, of British Columbia, influenced by the work of Dr. Hobbs, of London, and Dr. Roche, of Baltimore, has come to the conclusion that a very large proportion of female lunatics suffer from diseases of the pelvic organs, and that careful gynæcological examination "would send at least one patient to the hospital for every two sent to the asylum." Four inmates of the provincial asylum (all he has hitherto examined) were so affected. In one he removed the appendages and curetted the uterus and she recovered perfectly, physically and mentally, in two months. As a rule, the patients are ignorant of their physical condition and do not complain of pelvic pain or inconvenience. He concludes: "It would be interesting to continue the analogy in the treatment of the opposite sex. A very limited experience has shown a striking parallelism."—*Canadian Practitioner.*

The Electric Hæmostat.—Successful demonstrations are reported to have been given in London by Lawson Tait with his electric hæmostat, an instrument which, as its name denotes, is intended for the arrest of bleeding in surgical operations. A platinum wire arranged to carry a current is inclosed in the blades of a pair of steel forceps or any other requisite utensil, the wire being insulated by a bed of burnt clay. In practice a current of suitable voltage is turned on, the artery seized and compressed, and in a few seconds the tissues and arterial walls are so agglutinated that the passage of blood is rendered impossible. The temperature employed is about 180° F., showing a great difference between this and the electrical cauterizing instruments, and the necessity for a ligature is removed.

Trained Nurses in Jamaica.—Major-General Hallowes, who is commanding the troops in Jamaica, is endeavoring to raise money to provide two trained nurses for the military hospital there, the dearth of trained nurses having been severely felt during the late outbreak of yellow fever.

The Human Brain.—A German biologist has calculated that the human brain contains 300,000,000 nerve cells, 5,000,000 of which die and are succeeded by new ones every day. At this rate, assuming the correctness of the German's guess, we get an entirely new brain every sixty days.

Anecdotes of Syme.—Malcolm Morris relates the following story of Syme, at once showing the honesty of the man and his ready tact. He was fond of impressing on his pupils the propriety of always making an exploratory puncture before proceeding to remove the breast. On one occasion, before operating on a woman with a breast of stony hardness, he repeated his customary warning, adding that although in the case before them there could be no doubt that the disease was scirrhus, he would yet by way of showing an example of obedience to a salutary precept take the precaution which he wished them to employ in similar cases. Accordingly he plunged the needle into the patient's breast, with the result that a gush of pus took place. Instead of being disconcerted, Syme turned to the class and, with a little bow, said: "There, gentlemen, that points, in a manner which I didn't expect, the moral I wish to impress upon you." So struck were the men by the utter freedom from humbug thus displayed that they cheered the teacher who had turned his own mistake into a profitable lesson for them. Medical students are the most ruthless of critics, and only a really great man could have done this. Dr. Donald Maclean, of Detroit, an old pupil of Syme, says that Syme, though a most abstemious man himself, disliked the "unctuous rectitude" of perfervid teetotalers. Dr. Maclean remembers the case of a boy of not more than twelve years of age who appeared at the clinic, suffering from a peculiarly loathsome form of disease. Syme, with an expression of infinite disgust on his face, asked the youthful sinner the question, "Are you a teetotaler?" to which the little hypocrite replied, "Oh, yes, sir." "I thought so," quietly remarked Syme, with an expressive twinkle in his eye.

Bismarck's Physician.—Mr. Sidney Whitman, according to an English weekly, says that Schweninger's relations with Bismarck were even closer than those which united Gladstone and Sir Andrew Clark. Mr. Whitman, who met Dr. Schweninger at Friedrichsruh, says that there is something about the personal appearance of the professor—his dark searching eyes, his broad smile revealing a powerful set of small faultless teeth—which gives one the idea that the prowling man with the scythe is fain to slink off reluctantly when he encounters him. There is something in the grip of his hand which inspires confidence, and his jovial laugh is a tonic for any complaint. The fact that Schweninger did not despair of Bismarck's recovery from what was said to be a mortal illness by the great medical authorities of Germany some years ago, is alone sufficient to explain the reason of the affection Bismarck felt for him.

Longevity of Musicians.—A writer in a French newspaper the other day made an interesting announcement respecting the longevity of musicians. As a matter of fact, though a few of the most noted musicians of the world have died young—to wit, Mozart at thirty-five, Schubert at thirty-one, Bellini at thirty-three, Mendelssohn at thirty-eight, and Weber when he was but forty—quite a large number have lived to be very old men. Those who died between sixty and seventy years of age include Bach, Bulow, and Rubinstein. Living beyond seventy years came Gluck, Gounod, Handel, Liszt, Meyerbeer, Rossini, Spontini, and Wagner, while the great age of eighty-nine was attained by Auber and others. Dying at past eighty were Cherubini, Cramer, Lachner, Palestrina, Rameau, Schutz, and Taubert. The average age of musical celebrities is about sixty-seven years.

Colonization in the Tropics.—Benjamin Kidd, writing to the London *Times*, says: "The attempt to acclimatize the white man in the tropics must be recognized to be a blunder of the first magnitude. All experiments based upon the idea are mere idle and empty enterprises foredoomed to failure. Excepting only the deportation of the African races under the institution of slavery, probably no other idea which has held the mind of our civilization during the last three hundred years has led to so much physical and moral suffering or has strewn the world with the wrecks of so many gigantic enterprises."

Napoleon as Schenck's Predecessor.—Napoleon's opinion on the determination of sex was less prolix and more easily followed than the present theory of Dr. Schenck's, with which we are all familiar, if we may judge from a letter dated August 31, 1806, addressed to the Princess Augusta, the wife of Prince Eugene. In this epistle the emperor advises his sister, who was then in an interesting condition, to take good care of herself, and adds: "Try not to have a daughter. I will give you a receipt to this end, but you may not believe in it; that is, drink water and wine daily." This receipt is simple and much easier to follow than Dr. Schenck's. It appears, however, that it is either not infallible or else the princess did not follow it, for she had a girl.—*Le Nord Medical.*

Diagnosis of Infectious Diseases.—I believe the day is not far distant when the physician will diagnosticate the infectious disease to which he is called, not by the fever chart but by the chemical analysis of the urine, which carries off the bacterial alkaloids in solution, and he will treat and cure his patient by the hypodermic administration of the physiological and chemical antidotes of the known bacterial alkaloids.—Dr. Ernest S. Pillsbury, *Pacific Medical Journal.*

Health Reports.—The following statistics concerning small-pox, cholera, plague, and yellow fever have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending September 10, 1898:

Small-Pox—Foreign.

		Cases.	Deaths.
New York, Livonia	During month of July	1	
Waverley	During month of July	5	
New Mexico, Albuquerque	August 2d to September 4th	52	
Ohio, Put-in-Bay	September 6th	26 *

STATE AND MUNICIPAL CARE OF CONSUMPTIVES.[1]

BY S. A. KNOPF, M.D.,

NEW YORK.

MR. PRESIDENT, MEMBERS OF THE CONFERENCE OF STATE AND PROVINCIAL BOARDS OF HEALTH OF NORTH AMERICA: Your invitation to address you on the important subject of State and municipal care of consumptives, extended to me as one of the general profession in no wise connected with any State, provincial, or city board, has been a pleasant surprise to me. While I thank you for the high honor you have conferred upon me individually, I feel deeply the significance of your generous act, being fully aware that you wished above all to honor thereby the general medical profession. There has been of late years growing up in some parts of our country a certain antagonism between the appointed sanitary authorities and the profession at large. Your wish to listen to a humble representative of that great body of American physicians who are on the other side of the camp, who occupy no official position, who are, in other words, simply practising their profession, is perhaps the best evidence of your earnest wish to co-operate with the general profession in all that concerns the interest alike of patient, physician, and the public health.

For this I thank you, because it makes my task easier. To my mind there is nothing more difficult than to talk about tuberculosis, its cure or its prevention, without taking as the basis of one's discourse the absolute assurance of the co-operation of the general profession and the sanitary authorities. So in this spirit of harmony let us enter upon the consideration of our subject proper.

In a paper on the prophylactic treatment of pulmonary tuberculosis, read before the American Climatological Association at the meeting of the last medical congress in Washington, in 1897, I said: "To prevent pulmonary tuberculosis we must begin with treating the child *in utero*."[2]

Mr. President and gentlemen, the State and municipal care of consumptives must also begin with the child *in utero*.

This is not the place to discuss the prophylaxis in regard to the procreation of a tuberculous progeny, which must, according to our present conceptions of law and ethics, remain the delicate task of the family physician. The duty of the sanitarian and the government in regard to the consumptive poor commences with the care of the tuberculous mother after conception. All I may be privileged to say here is that, according to the experience of prominent obstetricians (foremost among whom I wish to mention my two late and much-regretted teachers: Professor Lusk, of New York, and Professor Tarnier, of Paris), intervention after a tuberculous conception for the purpose of cutting short the duration of gestation, and thus saving the mother's life, has proved disastrous in the majority of cases.

During my visits, some years ago, to many of the sanatoria[1] for consumptives of Europe and of our own country, I inquired into the results obtained by the hygienic and dietetic treatment in those places in cases of pregnant tuberculous patients, and I learned, to my surprise, that a goodly number of these women not only did remarkably well during their pregnant state, but bore healthy children and continued to improve generally. Dettweiler, Römpler, and Wolff[2] have kept some of these tuberculous mothers under their observation for years, and no relapses were noted. The only conditions, *sine qua non*, in such cases are the artificial feeding of the child, or, better yet, giving the latter the benefit of a healthy wetnurse, and a prolonged and persistent treatment of the tuberculous condition of the mother under the best hygienic surroundings. Thus, it seems to me, the best policy for the government would be to create institutions, which might perhaps justly be called "maternity sanatoria," where the tuberculous mother, coming from our tenement districts, should be taken at least a few months before her delivery, and should remain until some time after complete recovery from her childbed.

The beneficial effect on the woman's and child's constitutions through such an arrangement can hardly be overestimated. Leaving aside the physical well being thus largely assured to mother and child at a period when their organisms need the most tender care, the hygienic training which the mother will have received in such an institution will be of lasting utility to herself and child, to the family, and to the community.

These maternity sanatoria need not be situated at a great distance from the city. All that would be essential is that they should be erected on good porous ground, preferably somewhat elevated, and in a locality where the atmosphere is as pure as possible. The buildings should be constructed according to the principles of modern obstetrical science and modern phthisio-therapy. The physician in charge should be experienced in both these branches of medicine.

The knowledge gained by the mother in the maternity sanatorium will, in all probability, suffice for her to bring up the infant as a relatively strong child and protect it from the dangers of tuberculous infection. But the inherited predisposition may still remain, and at the time the child begins to go to school the State should again make provisions. I have learned by private inquiry that a pregnant woman who has the misfortune to be syphilitic or tuberculous has great difficulty in gaining admittance to maternities supported

[1] Contrary to the custom of many English-speaking people, especially in the United States, I call these establishments *sanatoria* and not *sanitaria*. The former (sanatorium), from *sanare*, to heal, gives a better equivalent to the German "Heilanstalt," the word used by the originator of this system (Brehmer). Secondly, the word sanitarium, from *sanitas*, health, is usually employed to designate a place considered simply as especially healthy, a favorite resort for convalescent patients.

[2] Answer to personal inquiry.

by private contributions. I know from official sources that tuberculous children are not only unwelcome in public schools, but are not infrequently refused admittance, on the ground of being afflicted with a contagious disease. If I am not mistaken, it was in Toronto[1] that the right of the municipality to refuse a tuberculous child admission to a public school was tested for the first time before a court, and sustained on the ground of the contagious nature of the disease.

I do not wish to question the wisdom of this judgment, but I should like to know what is to become of the child if its parents are too poor to pay for private instruction? The child cannot return to the public schools, for its disease is a chronic one and may last for years. If the municipality refuses the benefit of an education in the ordinary public schools to such a child, does it not become an imperative duty to provide special schools for tuberculous children?

Schools, however, in the ordinary sense of the word, would do but little good to such a child. In France, Belgium, and some other European countries, there have existed for years sanatoria for the treatment of tuberculous children, maintained by the municipalities. Attached to all these institutions are regularly established schools. To provide a place where tuberculous children and the children of tuberculous parents—the weaklings of the flock, as they are graphically called by my friend, Dr. Irwin H. Hance, of Lakewood—shall be taken care of becomes the duty of the government. In these school sanatoria the children will have a chance to be cured, if possible, of their disease or their predisposition, and at the same time they will receive the education which the State owes to all the children of the community. The majority of these school sanatoria may be advantageously placed on the seashore, for it seems a well-established fact that the tuberculous manifestations in childhood, which are most frequently observed as joint tuberculosis or tuberculosis of the bones or of the glands, do remarkably well in marine climates.

The selection of such children for sanatorium treatment would be the task of the school physician, and one should be attached to every public school. He, seeing the children daily, in order to prevent the introduction and propagation of acute diseases, will soon discern between the robust and well-nourished and the weak, dyspeptic, and not infrequently underfed pupils. These latter will, *ipso facto*, always be or become candidates for tuberculosis. If they are placed in time under good hygienic care, their chances of becoming strong and healthy citizens will be materially increased. For children suffering from pulmonary tuberculosis an institution could easily be annexed to each of the larger mountain sanatoria for consumptive adults, of which I shall speak presently.

But before doing so let us ask ourselves: Is there really need of the State and municipality taking care of the tuberculous poor adult? This question has been answered by the greatest sanitary authorities of all civilized countries with a most emphatic yes. Dettweiler,[2] Leyden,[3] and Liebe[4] have spoken for Germany; von Schrötter[5] for Austria; Grancher,[6] Letulle,[7] and Petit[1] for France; Weber,[2] Lindsey,[3] and Walters[4] for England; Hansen[5] and Saugmann[6] for Denmark and Sweden; and in the United States we have in Bowditch,[7] Hamilton,[8] Biggs[9] and Prudden,[10] Lee, Trudeau,[11] Flick,[12] Hinsdale,[13] Otis,[14] Shrady,[15] and others[16] strong advocates for the establishment of State and municipal sanatoria for the care and treatment of the consumptive poor.

The crowned heads of Europe, such as the Czar of Russia, the Empress of Germany, the Emperor of Austria, the King of Saxony, the King of Sweden, and the young Queen of Holland have placed the sanatoria for the consumptive poor under their high protection, and have opened their private purses for their support. The nobility and the leaders in finance, art, and literature have been eager to imitate the noble example set by their sovereigns, and the latter, too, have given freely toward the erection and maintenance of such institutions. Thus, in the countries just mentioned a number of establishments now flourish which are doing a world of good by curing the curable tuberculous cases and taking care of the hopeless ones, thus diminishing countless centres of infection. Let me advise again, as I have before,[17] the statesman, physician, or philanthropist who doubts the need of such institutions in the United States to visit the consumptive poor in the tenement districts of our large cities, and study the hygienic and social conditions of these sufferers in their surroundings. Let him watch some of the tuberculous families. After lingering a year either the mother or father dies of consumption, and the remaining partner, having become infected by nursing the companion, dies a year later, after having buried half of the children, who have succumbed to tuberculous meningitis.

I am sure these visitors will emerge from the dark, dreary rooms and the crowded, unclean houses which serve as habitations for millions of poor people thoroughly convinced of the urgent need of measures to

relieve these consumptive sufferers. Let these doubters also experience the difficulty of gaining admittance as a tuberculous patient into a general hospital supported by private charity, or let them watch the rapid decline the poor consumptive often makes, even if he has been fortunate enough to be admitted to a general public hospital, and they will become still more convinced of the urgent need of creating special institutions for this class of patients.

It will be clear to them that something must be done in the interest of the sick as well as in the interest of the still healthy portion of the community.

But how can this be done, and done effectually? What class of patients should the State or municipality take care of? Only the curable or only the incurable ones? Only the poor or also those of moderate means?

If any government is in earnest in its endeavor to combat tuberculosis effectually, besides its regularly enforced laws against bovine tuberculosis, its thorough hygienic and prophylactic measures against tuberculosis in man through sanitary regulations and public instruction, it must take upon itself the care and treatment of the curable and incurable cases of tuberculous patients, among the poor and among those of limited means. I mean here by limited means a financial condition which does not permit a tuberculous patient to enter a private sanatorium or to have at home such medical, hygienic, and dietetic care as will assure him the best possible chance of recovery.

The next point to be considered would be how to recruit the patients, and how to discriminate between the proper and improper cases, and thus avoid increasing the dreadful and degrading abuse of medical charity, from which we all, and especially the general practitioners, suffer so much in these days.

Permit me to present to you a few suggestions in connection with these problems. Just as there exists in nearly all States or municipalities a commission or a number of special examiners for the purpose of determining who is a proper subject for State care in an asylum for the insane, so should there exist a commission for the determination of admission to a municipal or State institution for consumptives.

Such a commission, composed of a certain number of general practitioners and health officers, should be aided in its work by the charity organizations. Each and every case should be investigated by a combined committee of physicians and laymen, for the following purposes:

1. To determine the applicant's condition by a medical examination.

2. To visit his home if he has been found tuberculous, and to institute such hygienic measures as seem necessary (distribution of pocket spittoons, disinfectants, etc.).

3. To examine the other members of the family in order to find out if any of them have also contracted the disease, and if so, to counsel proper treatment.

4. To report in full to the sanitary authorities concerning the condition of the patient's dwelling. Its renovation or even destruction may become imperative when it is evident that tuberculosis has become "endemic" there, owing to the condition of the soil or to other sanitary defects.

5. To determine the financial condition, whether the patient is or is not able to pay, and whether or not by his being taken to an institution the family will become destitute.

If the latter should be the case, it would become an imperative duty for the municipality to provide for the family. In many cases a letter of inquiry, sent to the former medical attendant of the patient, would materially aid the work of the investigation committee.

Any individual should have the right to present himself for examination, and every physician should be at liberty to recommend any person for examination to the board of his precinct or district.

The institutions needed to carry out this plan would be:

1. A centrally located reception hospital and dispensary. The dispensary should treat the ambulant tuberculous patients, whose admission into the sanatorium is impracticable or has to be delayed for want of room. These dispensaries should also serve the patient discharged from the sanatorium as a place to seek counsel, and thus aid in his continued improvement or guard against approaching relapses.

2. One or several city sanatoria, located in the outskirts and if possible in a somewhat elevated region where the atmosphere is known to be pure. Here all patients should pass through a preparatory sojourn before being sent to the mountain sanatorium. The more advanced cases would all be retained here.

3. One or several mountain sanatoria at no greater distance from the city than three or five hours by rail, at an altitude, if possible, of between one thousand and two thousand feet, on porous ground with southern exposure, and as nearly as possible protected against the coldest winds, preferably surrounded by a pine forest. A farm in the vicinity, where the thoroughly convalescent patients could do light work, might make the institution in a measure self-supporting. To this place the selected incipient and the improved cases from the city sanatorium should be sent to complete their cure. To the mountain sanatorium there should also be attached a department for children suffering from pulmonary tuberculosis.

4. Several seaside sanatoria for the treatment of children afflicted with tuberculous diseases of the joints and other tuberculous (scrofulous) manifestations.

5. A maternity sanatorium. Of the requirements of such an institution I have already spoken.

By this plan you will see that I am in favor of treating tuberculous patients near their homes, and in the same or nearly the same climate as that in which they will have to live and work after their restoration to health. My reasons for advocating such principles are founded on the experience of all modern phthisio-therapeutists, who have demonstrated that the hygienic and dietetic treatment in closed establishments is feasible and successful in nearly all climates. I know from personal observation that cures of pulmonary tuberculosis effected in our ordinary home climates, which are in the average not considered as especially favorable to this class of sufferers, have been more lasting and more assured than cures obtained in more genial climes. And I may perhaps say right here that, with all due deference to the opinion of others, I do not believe there exists any climate which has a specific curative quality for any form of pulmonary tuberculosis. Climate can only be considered a more or less valuable adjuvant in phthisio-therapeutics, but not a specific.

It is, furthermore, my firm conviction that for social and economic reasons the majority of tuberculous patients will have to be treated near their homes. Only by adhering to this principle can we expect to cope successfully with tuberculosis—this disease of all climes, but which is most prevalent in large centres of population, where civilization has seemingly attained the highest standard. For this reason a corresponding development of sanitary science and the widest diffusion of the knowledge of hygiene are indispensable wherever men mass themselves together in large urban communities.

That through the presence of properly conducted sanatoria for consumptives not the least danger can arise to the vicinity where such institutions may be placed, I have endeavored to demonstrate in several of my previous writings[1] by citing the official statistics concerning the mortality from tuberculosis for forty and for one hundred years, respectively before and after the establishment of sanatoria for consumptives in certain villages in Germany. To be brief, I will only summarize these statistics here by saying that in the two villages, Goerbersdorf and Falkenstein, where five of the largest sanatoria are situated, the mortality from tuberculosis has actually decreased among the village people more rapidly and more largely than anywhere else, it being now one-third less than before the establishment of those institutions. Thus we see that properly conducted sanatoria for consumptives not only serve as hygienic educators to individuals and families, but as instructors in hygiene to whole communities. The example in scrupulous cleanliness set by employees and inmates of such sanatoria thus bears the best fruits. The same cannot be said of open health resorts, where the regulations concerning the expectoration are less severe. In these places the mortality from tuberculosis has increased among the native population since they have been frequented by consumptives. I am able to substantiate this statement by letters addressed to me by Dr. Ballestre, of Nice, France, and Dr. Atkins, of Las Vegas, New Mexico, both health officers of their respective localities. Recent personal inquiries in some of the boarding-places in the Adirondacks where consumptives congregate, outside the jurisdiction of the sanatorium, indicate, I am sorry to say, the same condition there.

And now, Mr. President and gentlemen, let us in conclusion treat the most difficult part of our discourse, that is to say, the social and economical aspect of the tuberculosis problem.

Let us take for illustration a community of 1,000,000 inhabitants. With an average death rate of 25 per 1,000, one-fifth of whom die from tuberculosis, the community would lose 5,000 a year from this disease.

Some sanatoria claim as many as seventy per cent. of cures[2] when the patients are admitted to treatment in the incipient stages, and I have reason to believe that these figures are exact, for pulmonary tuberculosis in the earlier stages is indeed one of the most curable of all chronic diseases. But let us presume a percentage of fifty only. Thus if these 5,000 had been placed at the onset of their disease under proper treatment in sanatoria, 2,500 human lives would surely have been saved. Statistics have amply shown that tuberculosis is most prevalent among the poorer classes. The relation is about as two to one. So I believe that I am nearly right when I say that of those 5,000 over 3,000 at least are of the poorer classes, and of these 2,000 have died most likely in public institutions.

From personal experience gained in some of the larger general hospitals in Europe and in the United States I have learned that a tuberculous patient rarely makes a continuous stay in one hospital. He usually improves after his first sojourn and leaves, only to turn up after a few months in the same or another hospital for a second period of rest, and so on. But, all in all, the time he spends in general hospitals, to which he is usually admitted when in the advanced stage, is rarely less than fifteen months.

[1] "Are Sanatoria for Consumptives a Danger to the Neighborhood?" MEDICAL RECORD, October 3, 1896. Revue de la Tuberculose, Paris, vol. iii., pp. 313–319.

[2] Semiannual report of the Loomis sanatorium for consumptives, 1898.

According to the last published annual report of the commissioners of public charities and correction of the city of New York for the year 1895, the daily expense per capita in the general hospitals of that city is $1.16. Thus the patient costs the municipality up to his death $522, aside from the money expended on the family of the patient, should the latter have been its only bread winner.

The general hospitals claim few cures of pulmonary tuberculosis, and it seems almost as if this money had been uselessly spent, since a general hospital cannot even be considered a safe place for isolating a consumptive. If the same patient had, for example, been treated at the Adirondack Cottage Sanatorium or at a similar institution, and been sent there at an early period of his disease, he would have had sixty per cent. more chances of recovery, and would have cost only $1 a day, and that during a period of perhaps only six or nine months.

Thus two thousand tuberculous patients treated in the general hospitals in the city of New York, with very little chance of being cured, but with much chance of doing harm to their fellow-patients suffering from acute diseases, cost the city $1,044,000. Treated in sanatoria or special hospitals, with twenty to fifty per cent. of chances of recovery, according to the stage of their disease, and even if we should allow them just as long a stay in the special institution as we grant to the advanced cases in general hospitals, the cost would be only $890,000. Thus with a saving of at least $150,000 and the saving of hundreds of lives, countless centres of infection would be extinguished, which otherwise would endanger the families and neighbors of these tuberculous invalids.

But aside from that, think of the gain to the commonwealth by restoring to health the many bread winners whose families, under the present conditions, might become a burden to the community.

As stated above, these institutions should be open not only to the poor but also to those in moderate circumstances who can pay part of the expense. For this latter class of patients, many of whom for reasons of a noble feeling of independence hesitate to accept public aid, I have often wondered if a plan, something similar to the State invalidity insurance companies of Germany, could not be inaugurated in this country. There the moment an individual enters upon the career of an ordinary laborer or servant he is obliged to be insured against sickness, accidents, and old age. If he develops tuberculosis he is immediately sent to one of the many sanatoria of that country. The government authorities, who are at the head of this State insurance company, have long since learned that, through a timely treatment in a sanatorium, the tuberculous individual is most speedily and lastingly cured, and consequently with the least expense.

Dr. Weicker, of Goerbersdorf, to whose institution a great many such patients are sent by the government, writes me that the percentage of cures among these is higher than among the private patients. His latest statistics give a percentage of eighty of established cures, with only an average of seventy-six and one-half days of sojourn in the sanatorium. This marvellous result is to be explained by the fact that the government insurance officials send their patients to the sanatorium at much earlier periods than a private physician is likely to do.

Thirty-seven of these government insurance companies have, according to their published figures for 1897, collectively assisted 4,480 consumptives, of whom 4,432 were sent to subsidized sanatoria. Nearly all these State insurance companies contribute to the funds of such establishments; some have found it to their advantage to erect special sanatoria of their own. For the year 1897 these State insurance socie-

ties of Germany invested altogether 1,300,000 marks in sanatoria for consumptives, and for 1898 a fund of between three and four millions has been destined for that purpose.[1]

How would it be if one of our most thickly populated States, after having created a number of sanatoria, should try the experiment of a State insurance company against tuberculosis? How many families, even of the classes in fair circumstances but in which tuberculosis is dreaded on account of the disease having been the cause of the death of some of their members, would not gladly avail themselves of this opportunity—especially since the existing life insurance companies refuse applicants with a family history of tuberculosis? This opportunity, offered by the State, would mean giving to their children the certainty of being afforded the best possible chance of recovery, should they be taken down with the family disease. No matter at what age, as long as the individual remained insured, there would be the State sanatorium to receive and treat him. A payment of, for example, fifty cents a month from the birth of the child, would give to the State insurance company after fifteen years, with the accrued interest, a capital of nearly $150. By paying the aggregate amount up to the date of application, any predisposed individual might be insured at any time, and such an institution be called into life at once.

The greatest chance of a predisposed individual being taken sick is between the age of puberty and thirty. The chances of the disease becoming healed without ever having been discovered are between twenty and twenty-five per cent. I am in a position to verify this percentage by statistics which I compiled for my book on tuberculosis.[2] Besides reviewing the vast literature on the subject I addressed three hundred letters of inquiry to the leading pathologists of the world, and as a result I can say that out of every one hundred autopsies made on people having died accidentally, or of diseases other than tuberculosis, twenty to twenty-five showed evidences of healed tuberculous lesions (cicatrization or calcareous formation). The chances of this disease being cured in from six to nine months, if it is discovered at an early period, are at least fifty per cent. It is not necessary to be an insurance expert to see by these figures that the State would hardly be a great financial loser by creating such an insurance institution. But the greatest benefit which would accrue to the State or commonwealth through such an enterprise would be the paving of the way toward a complete State or municipal control of tuberculosis among the population which, owing to their social conditions, could otherwise not properly be cared for, and would constitute forever an impediment to the thorough prophylaxis and possible eradication of the disease.

To carry on the various State or municipal institutions to be erected, with a view to effectually stamping out tuberculosis, a large staff of competent physicians would be needed. These physicians should be paid for their labor. It is inevitable that through taking thousands of patients into such institutions the general practitioner will lose some of his income. Let the State compensate him by paying him for the service he may render in any of the institutions (sanatoria, hospitals, or special dispensaries) created by the State with the view of combating tuberculosis.

[2] Knopf: "Les Sanatoria Traitement et Prophylaxie de la Phthisie Pulmonaire." Second edition, Paris. G. Carré et Naud, éditeurs. Contained also in "Modern Prophylaxis of Pulmonary Tuberculosis and its Treatment in Special Institutions and at Home." Alvarenga prize essay of College of Physicians of Philadelphia for the year 1898.

To proceed with this work as soon as possible, I should suggest transforming some especially favorably located general hospitals into special hospitals for consumptives. Create sanatoria for children on the seashore, for adults in mountainous or at least in elevated and healthy regions. If your State or provincial funds are not large enough to meet the demand, appeal to some of the many generous and patriotic philanthropists, whose hearts and hands are ever open when there is a question of saving American lives. In 1896 Vaughan, writing on the restriction of tuberculosis,[1] said: "Of the 63,000,000 people living to-day in the United States, 9,000,000 or more will die of tuberculosis unless something is done to prevent it." Let us do that something—let us do it soon and let us do it well—so that with the dawn of the new century we may hope to see the tuberculosis problem solved, at least in North America; solved by the most humanitarian method, thanks to the combined efforts of physicians, statesmen, philanthropists, health officers of States, provinces, and cities, and the good will of an intelligent people.

ATYPICAL MALARIA AS SEEN COMING FROM OUR MILITARY HOSPITALS.

By D. W. WYNKOOP, M.D.,
NEW YORK CITY.

My object in bringing a paper on this subject before the medical profession is that for the second time in the history of this country a manifestatation of malaria, which formerly was rare in all our Northern and Western States, to-day is common there. It might well be called the soldiers' malaria of 1898. The severity of this form of disease and its fatality cannot be too strongly borne in mind, and the striking resemblance that exists between it and typhoid fever during certain stages, once seen, will not be forgotten.

I think I may say without fearing contradiction that the number of physicians living in this part of the country is few who have had more than the most fleeting and doubtful knowledge of what is commonly spoken of as Southern fever. This is undoubtedly because clinical experience has been lacking in recent years, and practitioners have felt no impulse to look up and fix in mind a disease which they never expected to be called upon to treat. Whatever original research has been done on the subject of tropical fevers in recent years we owe for the most part to foreigners, and the literature has rarely been translated, it being apparently sufficient for us to know that there were such things as West Indian fever, South American fever, and Mexican fever. To-day the scene has changed and we are confronted with a new type. An atypical form of malarial fever has been brought to our door: we simply are called upon to open our eyes. There are few physicians who have not already been called upon, or shortly will be, to treat the invalids of war who have come back home, bringing with them the plasmodium malariæ of Laveran.

The following description of the algid form of malaria is the summing up and boiling down of the various cases I personally have had under my charge, both in private practice and at the Vanderbilt Clinic. My information has also been gathered from those in charge of our hospital camps; in particular, Camp Wikoff at Montauk Point.

Definition.—An infectious disease characterized by: (*a*) sudden onset with few prodromal symptoms; (*b*) paroxysms of fever with no regular type as far as time is concerned; (*c*) the typical malarial chill usually

[1] New York Medical News, March 7, 1896.

absent; (*d*) gastric disturbance with enteritis; (*e*) a chronic cachexia with anæmia and enlarged spleen; (*f*) a tendency to coma and death in the third or fourth attack; (*g*) skin disturbances; (*h*) the crescentic form of hæmatozoa always found; (*i*) the presence of this form of plasmodium in the blood of those apparently cured of their attack.

Etiology.—One may question the mosquito theory of entrance of the organism into the body, as most of those recently active in the Cuban war are unanimous in saying that they encountered few mosquitoes while on the island.

Few sailors have contracted this algid type of malaria, except those who have had considerable shore duty while in Cuba. It has been practically confined to those in the army who have lived in Cuba, though some have undoubtedly contracted the disease while in camp at Chickamauga. In Alabama and several of our Southern States this form of fever exists, although it is rarely spoken of as malarial fever; they say there that a person dies of a congestive chill.

Duration of Incubation is very uncertain. Many who have gone through the campaign with no sign of the disease have had it develop after their return to the States. This may be accounted for by the fact that it was the practice of most of the soldiers to take from fifteen to thirty grains of quinine a day while in Cuba, but on their return home they ceased taking the drug. It is possible that this amount of quinine, although taken at irregular intervals, was sufficient to keep the disease from manifesting itself, yet not sufficient to eradicate it.

Symptoms.—Mode of onset. The patient generally says that he was feeling perfectly well up to 11 A.M. He went in bathing and returned to mess in an hour. After dinner he began to feel weak and he went to his tent to lie down. By 4 P.M. his head felt dizzy and he had pains in his back and legs. This pain continues with increased severity and his dizziness changes to headache. On his admission to hospital at 8 P.M. it will be found that his temperature is 15° F., his pulse 120, and his respiration 28.

Chill is usually slight and often absent.

Fever.—The rise in temperature is usually a rapid one, ending at 105° F., though in many cases it may go as high as 106° F., and in some a little higher; it ranges between 103° and 106° F. With the end of the rise in temperature we are not to expect a rapid fall. The temperature may stay at this high point or near it for an hour or two, and then slowly fall, taking from ten to twenty hours before it gets near normal. A drenching perspiration accompanies this fall and keeps up even after the temperature is below 99° F. The patient lies in a state of profound prostration. The second day after this we find an afternoon rise in temperature up to about 101° F. This continues with a morning fall for possibly a week or ten days, if no quinine has been administered during this period. The second high rise in temperature should be looked for about this time. It will act in the same way as the first, with the difference of being probably higher with greater prostration. There is no fixed duration of time between the high temperatures. As a rule it is from five to ten days, apparently being influenced by the general condition and resistance of the patient. We have a third high rise and usually a fourth, the intervals becoming shorter and shorter. Death usually follows the fourth rise of temperature.

Under the action of quinine (given hypodermatically by preference when we find hyperpyrexia) we are able to control this temperature and usually prevent any excessive elevation of temperature following the initial attack. It is on the strict and prolonged administration of this drug that success in dealing with cases depends.

Abdominal Symptoms.—The spleen is always found enlarged and more or less sensitive to the touch. In percussing over the abdomen we find tenderness in various parts—in some cases shifting from day to day, in others showing a persistence over the ileum—a point which causes one to think of typhoid fever, especially in consideration of several other symptoms I shall mention later on. The second day after the initial high rise in temperature we have usually gastritis and enteritis as complications. In many cases I have seen the stools almost characteristic of typhoid—the pea-soup variety and frothy. Under the action of quinine the stools become gradually darker and more firm. The patient's tongue is heavily coated but is moist. In many of the cases the kidneys refuse to do proper work, and in one I had suppression of urine for thirty-six hours.

Mental Condition.—After the first rise and fall of temperature the patient is left in a very apathetic and dejected condition. He takes little interest in his surroundings, and sleeps a good deal of the time. He has no desire for food but is always thirsty. With the second rise in temperature he becomes delirious. With the third and fourth he becomes comatose. Many patients who are apparently cured (though in reality not), after having been up and about for a week or two, will be brought into the hospital in a comatose condition, this having come on within less than an hour; and in this condition they may expire. This is by far the most important feature to remember in connection with this atypical form of malaria. The blame lies on the physician who allows his patient to go about before the protozoon is eradicated from the system. Many sudden deaths of soldiers on furlough in our cities can be put down to this score.

Skin Disturbances.—In some cases there has been an erythematous rash of short duration on various portions of the trunk, often on one hip. This rash was followed by itching of the part.

Blood Examination showed the plasmodium malariæ in every case. It differed from that in our ordinary form of malaria by the constant appearance of the crescentic protozoon. The examination of the blood of those who had one or two previous attacks and were at the time of examination feeling perfectly well and doing their ordinary work, showed in several cases the crescentic form of the protozoon. From this we might justly infer that patients having had one or more attacks of this atypical form of malarial fever could not be considered free from the same till examination two months after the last dose of quinine showed their blood free from these organisms.

Concluding Remarks.—One can easily understand how a physician could mistake this form of malaria during certain of its stages for typhoid fever. In fact I am convinced that many are at the present moment undergoing treatment for a supposed typhoid fever, when in reality the above condition exists. With the knowledge of hardship and exposure these men have gone through, and on account of their lowered vitality, we are more prone to make the diagnosis of an irregular typhoid fever than to consider the disease as a possible malaria. An examination of the patient's blood will enable one to arrive at a correct diagnosis.

LATENT CANCER OF THE STOMACH.*

By JULIUS FRIEDENWALD, A.B., A.M., M.D.,
CLINICAL PROFESSOR OF DISEASES OF THE STOMACH, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE,

AND

A. S. HOTALING, M.D.,
RESIDENT PHYSICIAN, BAY VIEW HOSPITAL.

The diagnosis of carcinoma of the stomach is at times very difficult. This difficulty is apparent in the one hundred and thirteen cases of carcinoma of the stomach collected by Guinard,[1] in which the diagnosis had been made in only thirty-four cases. These cases, however, were collected from reports in the *Bulletin de la Société Anatomique de Paris*, most of them being remarkable for some anatomical or clinical peculiarity in diagnosis. There are many cases of carcinoma of the stomach in which the cardinal symptoms are absent and yet the diagnosis can be made from other symptoms; there are other cases, however, in which not only are the cardinal symptoms entirely absent, but all other symptoms, if present at all, are so insignificant that they do not lead one even to suspect a carcinoma; such cases are known as latent cancer of the stomach.

There are two varieties of latent cancer: First, those cases in which the gastric symptoms are absent or so insignificant that they are masked by other general symptoms. Thus the carcinoma may be masked by some intercurrent disease, or secondary metastases from a primary gastric carcinoma may hide the primary disease. Secondly, those cases in which there are no symptoms whatever, general or local.

Of the first variety a large number of cases have been reported; of the second the cases are few. The pathological conditions leading to latency are that the growth be located on the anterior or the posterior wall of the stomach in such a position as to involve neither the cardiac nor the pyloric orifice, and that the surface of the tumor do not become ulcerated. When either of these orifices is involved, symptoms of obstruction are at once manifested; if there is marked ulceration, toxic symptoms are produced.

Latent cancers of the stomach have been observed by Cruveilhier and Barth, and cases have been reported from the clinics of Trousseau, Andral, and Guéneau de Mussy. Chesnel[2] has reported six cases; three of these were masked by pregnancy; in another case, in a man who had died suddenly from apoplexy, a cancer of the stomach was discovered at the autopsy; in still another case presenting the clinical symptoms of Bright's disease a similar discovery was made.

Raymond[3] reported a case in which there were no gastric symptoms whatever; there were a sudden and very high elevation of temperature and a general and apparently eczematous eruption. The true condition was revealed at the autopsy. In another case, that of a man aged fifty-six years, the only symptoms were marked cachexia and general œdema. The autopsy revealed a large carcinoma of the walls of the stomach, not involving the orifices.

E. Brissaud[4] relates a case of a man, aged fifty-seven years, who entered the hospital suffering with intense anorexia; there was much emaciation but neither vomiting nor any digestive disturbance. He continued in this condition for twenty-two days, when fever suddenly came on with intense pain in the chest. A purulent pleurisy was discovered; soon the joints became infected and there were other manifestations of pyæmia. The patient died and a large cancer of the lesser curvature of the stomach was discovered. Many of the joints were found filled with pus and the left pleura contained a large quantity of pus.

Brodeur[5] reports a case, that of a man, aged eighty-seven years, with a good antecedent history, who complained of loss of appetite, slight nausea, though not vomiting, and alternating constipation and diarrhœa. Œdema came on and he died. At the autopsy a large encephaloid carcinoma of the stomach was found not involving the orifices, but the greater curvature of the stomach was entirely destroyed and its wall was replaced by the spleen; the left kidney and the liver were also involved. In spite of the extensive ulceration there had never been vomiting or hæmatemesis or pain. This case is remarkable as showing how far the destruction of the stomach may go without producing any marked symptoms.

An interesting case is reported by Goldscheider.[6] A woman, aged sixty-one years, presented symptoms of a compression myelitis, the cause of which could not be determined. At the autopsy a carcinoma of the spinal column was discovered, which was secondary to a carcinoma of the lesser curvature of the stomach. In this case there were no symptoms whatever of gastric disturbance.

Hampeln[7] reports a number of cases. In one the

diagnosis of senile marasmus and arterio-sclerosis was made; in another pulmonary tuberculosis; in still another pernicious anæmia. In all of the cases carcinoma of the lesser curvature was found. In two febrile cases the diagnosis had been malaria and abscess of the liver.

Aron[8] demonstrated before the Medical Association of Berlin a specimen of latent cancer of the stomach. The patient, a man, aged seventy-eight years, had become emaciated and had œdema of the face and extremities, ascites, and fluid in the pleural cavities. Nothing could be determined by examination except the existence of an enlarged liver. At the post-mortem examination a large ulcerated carcinoma was found involving the greater curvature of the stomach.

Leichtenstern[9] reports three cases. In the first there was an acute compression of the spinal cord with paraplegia due to a secondary lesion in the stomach. This had not produced any gastric disturbance. In the second case the diagnosis of acute miliary tuberculosis had been made. There were ascites, abdominal pains, and symptoms of chronic peritonitis. At the autopsy miliary carcinosis of the peritoneum was discovered secondary to a primary scirrhous carcinoma on the posterior wall and greater curvature of

* Read at the annual meeting of the Medical and Chirurgical Faculty of Maryland, April 27, 1898.

the stomach. The third case was one of chronic nephritis. There was hypertrophy but there were no gastric symptoms except occasional vomiting. The trouble was believed to be uræmic. The patient died of uræmia, and at the autopsy besides the cardiac and renal lesions a carcinoma on the lesser curvature of the stomach was discovered.

Similar cases have been reported by Loiseaux,[10] Lafourcade,[11] Bossowski,[12] Gombault,[13] Lefebre,[14] and Bouveret.[15]

The case which we report is of considerable interest. A. W——, colored, aged seventy years, entered Bay View Asylum on March 15, 1897. He was in good general health, with an amount of arterio-sclerosis usual at that age. He at no time complained of feeling ill. On July 3d he died suddenly. The autopsy was held July 4th. The following is taken from the post-mortem report: Height, five feet five inches. No rigor mortis; much emaciation.

Heart. The mitral orifice admitted two and the tricuspid orifice three fingers; weight, two hundred and twenty grams. The anterior segment of the tricuspid valve was slightly thickened along its edge; the pulmonary segment was normal. There were patches of arterio-sclerosis along the base of the aortic segments of the mitral valve and a small calcareous deposit along the posterior segment of the mitral valve at the base. The aortic segments were slightly thickened. The coronary arteries were marked by sclerosis with a large deposit of calcareous material, causing them to be stiff and brittle. The right ventricle was four millimetres in thickness; left ventricle, eleven millimetres; aortic orifice, nine centimetres. There was marked evidence of fibrous myocarditis.

Lungs. The left lung was free from adhesions; weight, four hundred and fifty grams. Hypostatic congestion was noted in the lower lobes. The right lung weighed five hundred and twenty grams, and was congested in the lower lobe.

Kidneys. The left weighed one hundred and forty grams; its capsule was somewhat adherent and it was pale in appearance. The pyramids were well preserved and normal in appearance, the medullary rays could be made out, and the glomeruli were readily visible. There was evidence of parenchymatous changes. The cortex was four millimetres in thickness. The right kidney weighed one hundred grams; its capsule was rather adherent; it was the same in appearance as the left kidney.

The liver weighed twelve hundred grams and was normal in appearance. The left lobe was adherent to the lesser curvature of the stomach.

The most interesting condition was found in the stomach. In the region of the lesser curvature, occupying both anterior and posterior walls, was a tumor mass sixteen by eleven centimetres, varying from one-half centimetre in thickness and projecting into the cavity of the stomach. The tumor was slightly pedunculated, the free edge of the tumor in places overhanging the attached base as much as two centimetres. Nodular projections were scattered over the surface. There were two or three ulcerated areas on the surface of the tumor, from one to two centimetres in diameter. The mass extended into the cardiac orifice but did not involve it. Scattered over the mucosa of the stomach were a dozen small nodules, one centimetre in diameter; some were pedunculated. The mass had extended through the muscular layer of the stomach.

No evidence of metastases could be found in the neighboring lymphatics. On section a considerable mass of fibrous tissue was visible; on pressure a white pulpy material was expressed in the vicinity of the ulcer. The stomach was normal in size and position.

Microscopically the tumor was found to be an adeno-carcinoma. The cylindrical cells lined the ducts very regularly in some places; in others the arrangement was very irregular and many of the cells had undergone necrosis. The ducts were separated by connective tissue, which showed considerable small-cell infiltration.

PATHOLOGICAL REPORT OF A CASE OF CEREBRO-SPINAL MENINGITIS.[1]

By CHARLES R. GRANDY, M.D.,
NORFOLK, VA.

In the very earliest medical records we find accounts of meningitis and also a little about its gross pathological changes, but no distinction is made between the different varieties of this disease. Indeed, all diseases with symptoms somewhat akin were put down as identical, and their causes were scarcely looked into. To the discovery of the influence of bacteria in the production of disease and to the more careful study of the morbid changes thus produced are due our present increased medical knowledge and the advance of medicine in general. Medical men, in recognizing that "like causes always produce like effects," often seemed to forget that its converse, "like effects are produced by like causes," is not necessarily the case. Thus we can have the same symptom produced by a variety of causes. However, on looking closer we will also generally find some difference in symptoms. On this depends much of the confusion found in medicine, though in recent years a great deal has been done to clear it up. This confusion was especially marked in the cases of meningitis, and indeed it remains to some extent to the present day. Even as early as the beginning of this century, however, one especial class of meningitis was noted and separated from the rest. This came as an epidemic and involved the spinal as well as the cerebral membranes. It did not attack the dura, but involved the other two meningeal layers and also the surface of the brain and cord. This epidemic form is the only one of which we shall have to treat, though a few comparisons may be made with the other forms.

Since the science of bacteriology was founded and it was proved that germs could cause certain diseases, attempts have been made to classify meningitis according to the germs that produce it, and bacteriologists have searched for the germ which produces acute cerebro-spinal meningitis. Different authors have described different bacteria, many varieties being

[1] Read before the Seaboard Medical Society of Virginia and North Carolina on July 14, 1898.

usually found in the meningeal pus. Thus some have said the disease was caused by the ordinary streptococcus pyogenes; others claim that it is caused by the micrococcus lanceolatus pneumoniæ; still others claim that it is caused by the combination of the two. Although both of these germs can undoubtedly produce a meningitis, still they are two of the most common bacteria, and there is absolutely no proof that they are, separately or together, the cause of acute cerebro-spinal fever. Indeed, we know that they produce inflammations of very different forms, the streptococcus producing meningitis following injuries or middle-ear disease and the lanceolatus producing that form which often occurs as a sequel to pneumonia. Each of these is simply a cerebral meningitis, and each runs a different course from that of the cerebro-spinal form, and can in no way be confounded with it.

In 1887 Weichselbaum described a diplococcus which he had found in the meningeal pus of six cases of acute cerebro-spinal fever. He was, however, unable to reproduce the disease in animals. In 1895 Jager verified this discovery. Last April, Councilman read before the Medico-Chirurgical Faculty of Maryland a very interesting paper on this subject, describing this diplococcus, its method of culture, and its effects on lower animals. The author is sorry that he was unable to obtain the original paper, but quotes from the abstract of it in the MEDICAL RECORD. This bacterium is described as being a diplococcus of two hemispheres, separated by an unstained interval, and about the size of an ordinary pyogenic coccus. It stains by the ordinary methods, but is decolorized by the Gram method.

There seems to be absolutely no doubt that this diplococcus is the true cause of cerebro-spinal meningitis, and that any other germs found are mere concomitants, just as we find many cocci along with the tubercle bacilli in the sputum of a phthisical patient, though we should never dream of speaking of them as the primary cause of tuberculosis.

In the epidemic which occurred in Norfolk this spring, specimens from two cases came under the author's observation. In one case there was only some of the meningeal pus, in the other a complete autopsy was made. Both were undoubtedly cases of cerebro-spinal fever.

A short description of what was found in these two cases may be of interest to the members of this society, especially as cases of this comparatively rare disease have probably come under the observation of every member of the society within the last six months. No attempt will be made to give the symptoms in these two cases, but only the post-mortem findings.

Stained specimens of pus from the first case showed many pus cells. There were found monococci of medium size, also diplococci of equal-sized cells with their opposing faces somewhat flattened; these were about the size and shape of gonococci. A few streptococci were found, and in one field were seen two specimens, each inclosed in a pus cell, of three cocci forming a triangle. No micrococci lanceolati were found.

In this specimen the diplococci correspond to the organisms described by Weichselbaum as those causing the disease. It is also well to note that there were no pneumococci found and very few streptococci. It was a case of rapid course, in which the autopsy was made soon after death. The two bacteria last mentioned would probably have been found if sufficient time had elapsed for secondary infection by them to occur.

The second case was more carefully examined, but no clinical history of any worth could be obtained, as the patient was brought into the hospital in a moribund condition. The case was under the care of Dr. Newbill, to whom I am indebted for the specimens

Autopsy.—A young negro man, who had been dead about eighteen hours. The body was well nourished; rigor mortis marked. Arms, thighs, and trunk showed a small papular eruption; legs showed scars. The pericardium contained a small amount of clear fluid. The auricles and ventricles of the heart were distended by an ante-mortem clot. The heart muscle was in good condition; the valves were patent. The pleuræ were normal. Both lungs were congested and œdematous. The liver was enlarged and lighter in color than normal (yellowish). The kidneys were both enlarged; their capsules were slightly adherent; the markings were indistinct, especially in the right organ. They were paler than usual, but could hardly be designated as large white kidneys. The spleen was enlarged and greatly congested, being quite dark in color. In its substance were six or eight masses of grayish caseous material, surrounded by a capsule of fibrous tissue. The largest of these was three-fourths of an inch in diameter and involved the capsule, it being plainly visible from the outside. The stomach and intestines showed no change.

Brain. Beneath the arachnoid, both at the base and over the upper surface of the brain, as well as around the cord, was found thick pus. This pus seemed to follow the sulci and blood-vessels, but was especially marked at the base. The meningeal vessels were greatly engorged. The ventricles were filled with a clear serum (no pus); their vessels were engorged. The brain tissue showed post-mortem changes.

A blood-serum tube was inoculated with the meningeal pus. Pus and blood from the meninges were collected in sterilized tubes. The spleen and parts of the kidney and liver were taken. Bouillon was inoculated from meningeal pus and from the spleen. Rabbits were inoculated by injecting one-half of a cubic centimetre of the bouillon cultures into the muscles of the back.

One of the rabbits inoculated from a culture made from the meningeal pus had a large abscess and also some pneumonia, but no meningitis. The other suffered no ill effects.

The spleen and the blood-serum tube showed only saprophytic bacteria. The meningeal pus showed a variety of bacteria—staphylococci, streptococci in short chains, saprophytic bacilli, and several varieties of diplococci. One of these was undoubtedly the micrococcus lanceolatus: another, the one most commonly found, was made up of two cocci with their opposing faces somewhat flattened. These greatly resembled the gonococci. At times they seemed to be almost monococci, being separated by only a faint unstained line. Then there were diplococci, made up of two equal spheres, which were about the same size as the one last mentioned. Whether these merely represent stages of development of one organism, or are two distinct organisms, is a difficult matter to decide. These diplococci were stained by the ordinary methods, but were decolorized by Gram's method. They were, according to my way of thinking, undoubtedly the organisms described by Weichselbaum.

A microscopical examination of the kidney showed the epithelium of the canaliculi to be fatty, partly without nuclei, and with the cell outlines quite indistinct. There were also hemorrhages into the canaliculi in various places; the glomeruli were in pretty good condition, though somewhat shrunken. The spleen was filled with blood, and contained a large amount of pigment. In places were caseous masses surrounded by well-formed connective-tissue walls. These did not contain tubercle bacilli, nor did they show any of the other appearances of tubercles. No

other bacteria were found in the sections of spleen tissue. The liver also contained much free blood and pigment. In parts there was a deposit of amyloid material, though this had not progressed far. There were many leucocytes between the liver cells and around the gall ducts. The liver cells themselves did not stain well, but showed no especial changes. No gummata were found in the liver.

Anatomical Diagnosis.—Acute cerebro-spinal meningitis, acute nephritis, gummata of the spleen, beginning amyloid degeneration of the liver, congestion of the lungs.

Thus in both cases the diplococcus of Weichselbaum was found. In the first case no micrococci lanceolati and only a very few streptococci were found. In the second case (a case which in all probability had lasted much longer than the first, and in which the autopsy was performed at a much longer time after death had taken place) these other germs had had a much better opportunity of developing along with the true organisms of the disease.

It is generally supposed that the organism causing cerebro-spinal meningitis enters through the nose and the cribriform plate of the ethmoid. Both the streptococcus and the micrococcus lanceolatus are often found in the healthy mouth and nose, and could thus easily pass into the diseased meninges, which in health would be able to resist a single example of these germs.

Acute inflammation of the kidneys has been reported in several cases of this disease, though it does not seem to be a very common complication. It is interesting to note that before death both albumin and casts were found in the urine.

The changes in the spleen and liver are most interesting, though here we find a complication. The caseous masses found in the spleen were to my mind of syphilitic origin. They were not tuberculous, being quite different in structure and showing no tubercle bacilli. This diagnosis was further supported by the scars found on the patient's legs. The eruption on the body may have been a syphilide, or may have been the eruption so often occurring in cerebro-spinal fever. As the subject was very black, the differential diagnosis called for a more skilled dermatologist than the author can claim to be.

In other parts of the spleen, and indeed in all parts outside of the gummata and throughout the liver, were found blood and pigment (probably blood pigment) in large quantities. This was probably the result of the high fever, and possibly of the specific action of the disease.

Whether the small amyloid deposit in the liver was a sequence of the syphilis or of the suppuration in the meninges cannot be positively stated. Though we know that amyloid degeneration is at times found with syphilis, still it is even more often caused by prolonged suppuration. One theory of the deposit of amyloid material is that it is carried by the leucocytes from the point of suppuration, and deposited by them in the different organs. One author claims to have discovered it in the bodies of leucocytes and pus cells. Now if this be the case, why may not the amyloid material have been brought to the liver from the meningeal pus? Though it is impossible to prove that the amyloid degeneration is a result of the cerebral suppuration, it is still a very interesting find.

The large amount of blood and blood pigment in the spleen and liver, together with the renal hemorrhages and the large ante-mortem heart clots, shows a grave change in the blood due to a profound septic intoxication. Indeed, in the so-called fulminating form of the disease, when the poisoning is so great that the patient dies before there is time for the formation of meningeal pus, this change in the blood with its consequent hemorrhages is the only pathological change visible. Whether the diplococcus of Weichselbaum is in this form found only in the meninges or is generally disseminated throughout the body, I have not seen reported. In ordinary cases it is found only in the meninges, the other effects being entirely produced by its toxins, as is the case with diphtheria. It is probable that it is found only in the meninges in fulminating cases also. Thus the disease would seem to take its place as a parallel to the fulminating form of Asiatic cholera, in which there are almost no pathological changes found, and in which the cholera spirilla do not pass out of the intestine, though they cause death by rapid poisoning through their toxins.

TREATMENT OF SOME OF THE DISEASES OF CHILDREN TWO HUNDRED YEARS AGO.[1]

By ROBERT REYBURN, A.M., M.D.,

PROFESSOR OF PHYSIOLOGY AND HYGIENE, MEDICAL DEPARTMENT, HOWARD UNIVERSITY, WASHINGTON, D. C.

THE present inhabitants of our modern cities have become so accustomed to the benefits conferred upon them by the recent discoveries in medical science that it is very difficult for them even to imagine the vast contrast in the treatment of disease two hundred years ago, when compared with our treatment at the present time.

It should be remembered that two hundred years ago the great discovery of vaccination by Dr. Jenner in 1796 was unknown, and small-pox still continued to slay its uncounted millions. It is quite unnecessary and would be out of place in this paper to advocate vaccination, and we will only say that vaccination is admitted by all medical authorities to be the greatest blessing that the science of medicine has ever given to mankind.

The first authority we will quote on children's diseases will be Dr. Thomas Willis, an eminent physician of England. He was born in 1621 and died in 1674. He wrote several medical works, one on the anatomy of the brain and one on convulsive diseases, including epilepsy and scurvy. From the latter, page 143, we make the following quotation concerning the treatment of epilepsy:

"A Man in this Neighborhood, had all his Children dead of Convulsions, within three months after they were born. At length, to prevent the same Fate in a Son of his that was new-born, he thought proper to try the Power of Medicine. I was called to him a few days after the Birth, and ordered an Issue in the first Place to be made in his Neck, and that two Ounces of Blood should be drawn next Day at the Neck, by the Application of Leeches. I advised besides, that for three Days before each Change of the Moon, and again before the Full, about five Grains of the following Powder should be given him Morning and Evening in a Spoonful of the Julap.

"Take prepared Human Skull, the Root of Male-Peony, of each one Drachm. Pearls in Powder, half a Drachm. Mix them all together, and make a very fine Powder.

"Take of Black Cherry-Water, three Ounces. The Antepileptick Water of Langius, an Ounce. Syrup of the Flowers of Male-Peony, six Drachms.

"I likewise ordered the Nurse to take a Draught of Whey, in which the Roots and Seeds of Male-Peony, and the Leaves of Lilly of the Valley had been boiled, twice every Day at the same Hours.

"The Child continued well about two Months, and then began to be troubled with Convulsive Disorders;

[1] Read before a joint meeting of the Medical and Anthropological Societies, Washington, D. C., May 14, 1898.

upon which Account the same Medicines were again repeated in larger Doses, both to the Child and Nurse. Blisters were applied behind the Ears, and he was again bleeded at the Jugulars with Leeches. By these Means he got well again within two or three Days; and about four or five Months afterward, when the same Disorder returned, he was cured by using the above Medicines. After he was seven Years old, the Convulsions entirely left him; but about the lower part of the Back Bone, an indolent Tumor arose. This Tumor occasioned a Distortion of the Vertebræ, which was succeeded by a Weakness of the Limbs, and at length a Palsey."

Extraordinary and even barbarous as the above treatment seems to us, yet in order to show that it was the usual treatment for epilepsy in that day we will now give a quotation from the book of Dr. Walter Harris on children's diseases, who was physician in ordinary to King William the Third of England. He was born in England in 1651 and died in 1725. In his article on epilepsy in the above-mentioned book, page 148, he says:

"A girl eleven years old of a sanguine constitution, and troubled with very long and violent Epileptic Paroxysms, desired my advice the Eighteenth of December, 1701. For six months she had suffered two severe Paroxysms each day. The Paroxysm was in this manner: She fell first down as if dead upon the floor or bed; whence this disease is called the Falling Sickness: and after remaining motionless for a little while, she tossed her limbs here and there with great force and violence, attempting to beat herself with her hands. She frequently bended her head downward with strong Convulsions, and flung it backward with such force, as if she designed to dash the hind-part of her Skull to pieces."

After giving this vivid and accurate picture of epilepsy he says: "I prescribed for her the following powders: Take of prepared Earth Worms One Ounce. Human Skull prepared Two Scruples (forty grains). Mix them and divide into twelve powders, one to be taken twice a day in a spoonful of Cephalic Julap."

The next authority quoted will be Dr. Richard Wiseman, who lived about two hundred years ago, and who was the physician to King Charles the Second of England. He wrote a number of treatises on various medical and surgical subjects, and from his treatise, page 241, on the king's evil or scrofula, the following paragraph is taken. After prescribing various remedies he says:

"But where that does not agree we prescribe distilled milk of which this sort may serve as an example. Take of best Sarsaparilla one pound. Shavings of Hartshorn six ounces. Leaves of Agrimony and of both kinds of Fluelline, of each three handfuls. White and Red Saunders, of each two drachms. English Liquorice a pound. Garden Snails one hundred. Earth Worms one pound. New Cows Milk two gallons.

"Distill them according to art and to three pounds or pints of the distilled liquor add two ounces of prepared Crabs Eyes. Let him take of this to the quantity of four ounces at a time adding to each dose some quantity of Cinnamon Water."

Dr. Wiseman was also, it is said, a believer in the efficacy of the king's royal touch as a cure for scrofula, but he does not mention it among the remedies in the article we have quoted.

But let us return for a moment to Dr. Harris' book on diseases of children, and see his treatment of fever, on page 44.

"To a child of a year old labouring under a fever or tormented with gripes I commonly prescribe in the following manner: Take Compound Powder of Crabs Claws, Prepared Pearls, of each one drachm (sixty grains). Mix them and make a powder to be divided into six equal parts. The child must take one of these immediately and let it be repeated (if the case require two hours thereafter and then every fourth hour)."

Dr. Harris could not have prescribed such remedies as these for any except rich patients, and we know now that crabs' eyes and prepared pearls are chemically nothing but carbonate of lime or chalk. The same quantity of prepared chalk given to the patient would have answered every medicinal purpose equally as well as these costly powders.

Thomas Sydenham, who was born in England in 1628 and died in 1689, was one of the most famous physicians of his time. Advocating as he did in the treatment of fevers and eruptive diseases, such as measles, small-pox, etc., of children, the use of cool air and other cooling methods of treatment, he was far ahead of his time. In his monograph on measles he gives a very good description of the disease, and a good deal of his treatment would be deemed judicious at the present day. However, toward the end of his article he says, page 175:

"If after the measles are gone off, a Fever, difficulty of breathing, and other symptoms that indicate a Periphneumony (Pneumonia) to succeed, a good quantity of blood must be taken from the Arm, and if there be occasion, the bleeding must be once or twice repeated at proper intervals."

He also says, farther on in the same article: "The Diarrhœa which comes after the Measles is cured by bleeding."

In his article on small-pox, page 167, he says: "If on the eleventh day of the Disease, or on any day following it, the Suppurative Fever comes on, and rises to such a height, with sickness, restlessness, etc., that it is not to be subdued by repeated Paregoricks, and the Patient seems to be in imminent danger. In such a case you may let blood (bleed) to a considerable quantity, and repeat the bleeding twice or thrice on following days, if there be a necessity for it, but not otherwise."

We can imagine the sensation that would be produced by any physician in our day, attempting to bleed a child suffering from either measles or small-pox.

Dr. Burton, who was contemporary with Dr. Harris, wrote an interesting monograph on chin cough, or whooping-cough, as it is called in our day. After giving a fair description of the disease, on page 191 he says:

"When I am called, if the child be in danger of being convulsed, in the first place, in order to gain time I let some blood, which I would not otherwise do, because it is contrary to the second indication, and those children who were bled or much purged, were always longer in recovering, than those who had not been bled at all."

This last remark, by the way, seems to manifest that Dr. Burton had good powers of observation. On page 193, he says:

"I ordered a Scruple (twenty grains) of Contharides (Spanish Flies) and as much Camphire [camphor] well rubbed together, to be mixed with three drachms of Extract of Bark (one hundred and eighty grains), of which composition I gave the Children eight or nine grains every third or fourth hour in a spoonful of some simple Water or Julap, in which I had dissolved some balsam capaivy."

The children of the people who lived two hundred years ago must have been under better discipline than ours of the present day, or they never could have been induced to swallow such nauseous medicines. Finally, this brief and imperfect survey of the treatment of some of the diseases of children two hundred years ago serves to demonstrate very forcibly the fact that our children have fallen upon happier times in being born in an age of enlightenment and progress in medi-

cal science. We ought not to forget, however, that we owe a vast deal to our forefathers in medicine. They were without all the instruments of precision we possess. They were destitute of all the microscopes, stethoscopes, and thermometers, that aid us so largely in detecting and recording the diseases of internal organs. Without these aids, by their persevering labors the vast accretions of knowledge were accumulated, on which has been erected the glorious fabric of modern progressive medicine.

A NEW METHOD OF APPYLING A PLASTER-OF-PARIS SPLINT TO AN ANKYLOSED KNEE-JOINT OR TO A FRACTURED LIMB.

By H. M. HALL, M.D.,

BUTTE, MONT.

Almost every practitioner no doubt will have observed the difficulty in applying a plaster-of-Paris splint to an ankylosed joint when the hamstring tendons are tensely contracted and maintain flexion of the limb, which can be reduced only by applying considerable force. To overcome this difficulty the following simple device will be found effectual: The patient, having been anæsthetized, is drawn down until the buttocks reach the edge of the table, and the heel of the affected limb is placed on pillows on an adjoining table. This leaves a space between the two tables in which the operator can work. After the limb has been extended by manipulation, it is kept in a position of complete extension by the following method: A strip of cheesecloth or common domestic cloth, one foot wide and two feet long, is cut or torn into a many-tailed bandage—four, six, eight, or ten tails, as may be required. The tails are cut or torn to within two inches of the centre, the long way of the bandage. The joint having been well padded with cotton batting, weights such as sadirons are tied to each strand, when the bandage with the weights attached is put astride the joint; sufficient weight should be applied fully to extend the limb. (In the last case in which I applied this splint it took eight sadirons to keep the limb fully extended.)

I apply the plaster-of-Paris splint in the following manner: Commencing low down on the foot or leg, as may be required, as when there is tense contraction in the hamstring tendons, I bandage from the foot up the limb. When I come to the many-tailed bandage and weights I pass the plaster-of-Paris bandage in and between the strands and proceed on up the thigh the required distance. As the bandaging progresses, the strands of the many-tailed bandage at the knee-joint are pressed by the plaster-of-Paris bandage into small round cords. After sufficient plaster-of-Paris bandage has been applied, the limb is allowed to rest in the fully extended position with the heel on the pillows until the plaster has set, which is usually in twenty or thirty minutes. The tails sustaining the weights are then cut off close to the now firmly hardened plaster splint, when it will be found that the ends have retracted within the plaster cast, leaving small holes corresponding to the number of strands. These holes are useful in ventilating the joint, and do not impair the strength of the cast at all. In the course of one, two, or three weeks the splint can be taken off, when at that time the tendons are usually sufficiently stretched. If the tendons are not found sufficiently stretched, another splint can of course be applied in the same manner.

By applying plaster-of-Paris splints in this manner I have been able to reduce and keep in extension ankylosed joints when I could not have done so by any other means. This method is preferable to performing tenotomy, as recovery is much more rapid and complete.

The same principle being applied to the reduction of simple or compound fractures of the thigh, leg, arm, or forearm, when there is sagging or other angular deformity which is difficult to correct, the fractured member can be suspended in a sling or a swing made with the many-tailed bandage, the tails being torn to within one inch of the centre. The reduction of the deformity is effected and maintained by an assistant, who makes traction on the fractured limb. When the plaster-of-Paris bandage is applied in the same manner as before described, the strands of the many-tailed bandage sustaining the fractured limb will be found to have turned into round cords. The strands, having been cut away close to the cast, will recede within the same, and as the many-tailed bandage is outside of the dressing enveloping the limb it does not cause pressure. I have also used this method of applying the plaster-of-Paris splint after Phelps' operation for club-foot. By having assistants make traction in opposite directions with two bandages I have thus secured the foot in more complete eversion than by any other means.

I have also utilized this principle in the application of the plaster-of-Paris jacket. My method is to tack cheese or domestic cloth over the open end of a common dry-goods box, the box being long enough to suspend the patient his entire length on the cloth. Laying the patient on the cloth I find where the jacket is to come, and after I have padded all projecting points I cut the cloth on the top of the box into strips an inch and one-half or two inches wide, taking out every other strip. This leaves enough strands to sustain the weight of the body and makes the application of the plaster-of-Paris bandage much more easy. When all is ready for the application of the plaster-of-Paris dressing, two assistants, one holding the head, the other the feet of the patient, make traction in opposite directions and thus overcome the deformity to the required degree. The plaster-of-Paris bandage is applied from below upward, and the pressure of the same as before turns the sustaining strands into rounded cords. If the weight of the patient is so great that the strands do not readily round into cords, they can be twisted by applying a forceps to the middle of the same. As the suspension bandage is entirely outside of the protective dressing, this does not inconvenience the patient at all; and when the plaster-of-Paris jacket is cut open in order to apply the lacing apparatus any prominent ends of the bandage that might cause undue pressure can be cut off.

I also employ this same principle, of bandaging between the tails of counter bandages, in applying plaster splints and in making overcorrection after osteotomy for knockknee and bowlegs. The advantage of this method of applying plaster-of-Paris dressings will be better appreciated and the method will be generally used after it has once been tried.

Prophylaxis and Treatment of Ophthalmia Neonatorum.—Of the 300,000 blind in Europe, 30,000, or 10 per cent., owe their infirmity to ophthalmia neonatorum. This is so alarming that it behooves us to seek some remedy. According to M. Galezowski (*Revue d'Hyg. et de Pol. Sanit.*, April, 1898) three conditions are indispensable in order to effect a cure in this disease: (1) Cauterization of the conjunctiva twice daily. (2) Continuation of the treatment from the beginning to the end of the disease. (3) Rigorous observation of the laws of antisepsis. In 1,490 cases of purulent ophthalmia in the newborn, Galezowski has found that 389 patients have lost their sight.

Progress of Medical Science.

The Treatment of Infected Hair Follicles. — Dr. Eddowes read a paper on the above subject at the meeting of the British Medical Association, and said that "the hair follicles might be regarded as elastic tubes guarded by funnel-shaped valves, composed of prolongations of the horny layer of the cuticle into their mouths." He had obtained very satisfactory results from the application of a strong solution of phenol when the follicles were inflamed, *i.e.*, in conditions of the follicles characterized by redness at their orifices and a slight tendency to bulge in the form of a minute vesicle, though it was useless for superficial or slack vesicles or for deep infections, such as occurred in indurated acne. It was obvious that the larger the amount of fluid contained in the follicle the greater would be the interval between the living tissue and the hair forming the plug, and the better would be the opportunity for diffusion to take place. Following this principle in practice, Dr. Eddowes attempted in the first place to excite rapid effusion by the application of various liniments and ointments, and before the vesicles had a chance of giving way and thereby releasing the back pressure into the follicle he applied phenol or some other powerful antiseptic.

Surgical Treatment of Tuberculosis of the Bladder.—Dr. E. Desnos says that although tuberculosis of the urinary passages often remains localized to the organ originally attacked, operative proceedings, such as curetting or total resection of the vesical mucous membrane, were generally followed by no good result, and were sometimes followed by generalization of the infection throughout the urinary apparatus. Nevertheless, painful forms of tuberculous cystitis can often be dealt with satisfactorily by suprapubic cystotomy, but in these circumstances care must be taken to leave the vesical mucous membrane untouched, whatever lesions it may present. The operator must be content with draining the bladder. If the patient is willing to put up with the inconvenience of a fistula for a long time—at least a year—not only does the pain diminish or cease altogether but nearly all the lesions undergo a temporary arrest, owing to the permanent relief of the congestion of the bladder walls and the abolition of micturition through the natural passage. When operation of any kind is contraindicated, recourse must be had to instillations of sublimate and injections of guaiacolated oil and to general treatment.—*British Medical Journal.*

Heart Complications in Diphtheria.—Hibbard finds that less than one-half of the patients in whom the pulse rate exceeds 100 recover. The pulse rate and the mortality appear to be very much in a direct ratio to one another, and recovery is comparatively rare with rates above 150. Extreme slowness of the pulse is less significant, but in children bradycardia does at times presage evil. Variations of rhythm and volume occur in about ten per cent. of cases, and are a useful premonition of cardiac complications. A systolic murmur at the apex of the heart is heard in about one case in ten. This is commonly due to mitral insufficiency caused by dilatation, but in rare instances to an endocarditis of diphtheritic origin. The murmur is not in itself a serious matter, but if an increasing area of cardiac dulness and accentuation of the pulmonary sound indicate dilated ventricle, the outlook is less favorable.—*Boston Medical and Surgical Journal.*

Carbolic-Acid Poisoning.—Toxic effects have occasionally resulted from the use of carbolic acid as an antiseptic. At a recent meeting of the Société Médicale des Hôpitaux, reported in *The Lancet*, Dr. J. Comby related the following case: A child, aged five years, was treated for otorrhœa with carbolic acid. Injections of one and one-half per cent. were employed six times a day. After the last injection in the evening five drops of glyceride of carbolic acid (five per cent.) were instilled, and in addition the ear was bathed with the first solution. This treatment was scrupulously carried out for ten days, when the otorrhœa stopped; but two days afterward the child had persistent hæmaturia and headache. Careful physical examination revealed no other signs of disease and the general condition was satisfactory. Symptoms of acute nephritis, pyrexia, œdema, etc., were absent; there was no evidence of tuberculosis and the microscope showed that the case was not one of hæmoglobinuria. Dr. Comby therefore concluded that the hæmaturia was due to poisoning by the carbolic acid, which had been so sedulously used. The hæmaturia ceased in about a fortnight. Carbolic acid should be carefully used in the case of children, as they are especially susceptible to it.

Technical Details in Asepsis.—At a recent meeting of the Berlin Medical Society a discussion took place with regard to a paper read by Schäffer on asepsis. Dührssen said that the principle of asepsis was so simple that it could be appreciated by every one. The practical realization of this principle, however, was by no means simple, and required the careful consideration of each individual surgeon. He employs an aseptic operating-coat, which he removes from the sterilizing-chamber, having previously washed his hands with a nail brush. The lid of the chamber is raised by an assistant, who is not allowed to touch the coat. The process of buttoning is accomplished by a second assistant. Lister's theory of the infection of wounds by the access of air was considered to have a wider significance than infection by contact. In this connection the author stated that it was most important to see that all bleeding had stopped before the wound was closed, as blood accumulations formed a most favorable medium for the growth of bacteria. In peritoneal operations this was most important. Cases which did badly usually showed post-mortem signs of blood extravasations in those parts which had been subject to operative treatment. Asepsis (according to Schäffer and Dührssen) at the time of operation would not insure a good result unless all bleeding points had been secured before the wound was closed.—*British Medical Journal.*

Tuberculous Laryngitis.—Dr. Ellet Orrin Sisson (*Medical News*, April 9th) concludes an article on the above subject as follows: "To the microscopic investigations and to them alone is due the present thorough knowledge of its pathology. No one line of treatment can be laid down at the present time. There is too great a tendency on the part of the medical profession at large to place this disease in the list of incurable affections and to use only palliative treatment, and not take the interest that it should in the reports from the few untiring investigators who, in the face of apparently insurmountable obstacles, are endeavoring to find some cure for this dread malady. When we stop and think of the progress that has been and is being made in the treatment of other diseases as destructive in their nature as this, and which were less than ten years ago classed with it as incurable, we are justified in predicting that the time will come, and that it is not far distant, when laryngeal tuberculosis will take its place among them, and be classed as a curable disease."

The Effect of Alkalies on the Gastric Secretion.—Hayem states that alkalies given for some time and in sufficient doses, so far from curing hypersecretion of hydrochloric acid, are the most powerful agents in producing it. This is especially true of bicarbonate of sodium. They produce this effect after being absorbed and during their excretion. That it is not due to their local action on the gastric mucosa is proved by the use of mineral waters, which aid the absorption of alkalies and so produce hyperchlorhydria more readily than alkalies alone. The above is true only if the gastric glands are numerous and active. If the mucosa is atrophied, instead of raising the digestive power of the gastric juice with a tendency toward hyperchlorhydria, alkalies depress and aggravate the hypopepsia.—*British Medical Journal.*

Renal Calculus: the Difficulties and Errors in Diagnosis in their Relation to Exploration of the Kidney; Unsuspected, Quiescent, and Migratory Calculi.—Dr. Henry Morris (the Hunterian lectures on "The Surgery of the Kidney," *British Medical Journal*, April 9th) says the conclusions at which he has arrived are the following: (1) That the aim of the surgical treatment of renal calculus should be to extend the application of nephrolithotomy, and thereby restrict the necessity of nephrotomy and nephrectomy. (2) That more frequently than not the failure to find a stone is not in reality a failure of treatment, because there are so many curable morbid conditions which mimic renal calculus, and which are discoverable only by exploration. (3) That the theory that a stone in one kidney, whether that kidney is itself painful or not, reflects or transmits pain to the opposite kidney is quite unproven; that it is a dangerous theory, calculated to lead to very erroneous practice; and that the surgical principle with regard to exploratory operations should be that with pain, paroxysmal or continuous, on one side only, the kidney on the painful side should be explored. (4) That nephrectomy for calculous conditions is not often called for, and should be done only in exceptional cases. Nephrotomy for calculous pyonephrosis is the proper operation, at any rate as a primary operation, because of the frequency of double calculous disease. Experience has shown that kidneys from which stones weighing eight hundred and thirty grains and thirteen hundred grains have been removed are functionally sufficient to maintain life during the blocking of the ureter or suspended action of the kidney of the opposite side. (5) That nephrectomy while the opposite organ is occupied by calculus is fraught with the greatest danger to life; whereas nephrectomy after the opposite kidney has been freed of stone will probably be followed by recovery from the operation and possibly by very good health for many years afterward. (6) That when renal calculus causes reflected or transferred vesical or ovarian pain, the removal of the calculus will be followed by complete cure of the bladder or ovarian symptoms. (7) That in some cases renal-calculus conditions are attended by very remarkable nervous symptoms, sometimes with, sometimes without, high temperature, and that information as to the cause of these symptoms is needed. (8) That unsuspected renal calculi are a source of very real danger to their possessors; and when, whether by accident or by the systematic examination of the urine, we have cause to suspect the presence of a calculus, we should recommend its immediate removal, regardless of the fact that it is not causing renal or transferred pain. (9) That quiescent calculus is as dangerous to the individual as unsuspected calculus, and ought to be removed by operation. (10) That the hitherto accepted teaching, that a renal calculus, if causing only mild symptoms or attacks of severe colic of only recent occurrence, should be treated on the expectant plan, ought to be discarded as unsound in theory and dangerous in practice. (11) That the same principle should be applied to renal calculus which has long been the rule in regard to vesical calculus—namely, when suspected it should be searched for, when known to exist removed, without waiting in the hope that it may become encysted or spontaneously expelled. (12) That the very low mortality of nephrolithotomy puts this operation upon the same footing for renal calculus as lithotrity in the most experienced hands for vesical calculus.

The Surgical Treatment of Pyloric Obstruction, with an Account of Twenty Cases, and of a New Way of Performing Gastro-Enterostomy.—Dr. F. T. Paul (*British Medical Journal*, June 4th) remarks that stenosis of the pyloric end of the stomach is due to (1) congenital insufficiency; (2) obstruction from the external pressure of tumors, bands, etc.; (3) reflex spasm; (4) fibrous contracture; (5) cancerous and other growths. Several operations have been suggested for the cure of fibrous stricture, including pylorectomy, divulsion, pyloroplasty, and gastro-enterostomy. The conclusions at which he arrived regarding the four operations, of which twenty cases constituted his personal experience, were the following: Divulsion should be reserved for very exceptional cases, other and better methods having almost entirely excluded it. Of the other three operations pylorectomy is likely to be the best method of giving relief in a small percentage of cases, and though nothing can compete with pyloroplasty when circumstances are favorable to its employment, there always remains a considerable number of cases in which gastro-enterostomy alone is available. This operation must remain the most important one, because it is always practicable when the others prove impossible. Attention should be turned therefore to improving it. Dr. Paul proposed another plan, as follows: The stomach and bowels having been exposed, a longitudinal incision is made in the intestine—about two inches—through the peritoneal and muscular coats only. These are reflected with a small, curved, blunt dissector over an oval area, having a diameter of about one inch in the centre. The exposed submucosa is then rubbed about half a dozen times with a stick of zinc chloride, being well dried between each application, when it assumes a gray, dead look. The bowel is now wrapped in a piece of moist absorbent wool and laid to one side, while the stomach is dealt with in an almost similar manner. In the preparation of the stomach for the anastomosis, instead of a linear incision being made, an oval patch of musculo-peritoneal coat is excised; the muscular coat being so much thicker in this organ, it is rather in the way if only reflected, and what is of more importance is that the loss of substance helps to prevent subsequent contraction of the opening. Both the wounds having been duly cauterized, they are brought together, and a continuous suture of the finest green gut or silk is run around the edges, not, of course, penetrating the mucous membrane, but picking up as far as possible the tough submucous coat. Finally, a few Lembert or Halsted sutures are generally desirable, especially in anterior gastro-enterostomy. The mucous and submucous coats soon slough and disappear, and good firm union takes place. The features of this operation, which it is hoped may be reckoned as advantages, are: (1) The effect is one of pure traumatism. The viscera not being opened, all risk from such sources is avoided. (2) No foreign body is used. (3) The time occupied is less than for a suture operation, though more than for Murphy's. (4) The anastomosis resulting from loss of tissue should be more durable than by the majority of methods.

Appendicitis.—Dr. Spencer Graves (*International Journal of Surgery*, May) says: "I prefer, when seeing a patient in the beginning of an attack presenting the ordinary symptoms, to treat it medicinally for a varying length of time, for the following reasons: (1) There are cases, a small percentage, that may be relieved in this way, the appendix returning to its normal condition. (2) In the interstitial form or in recurrent appendicitis I would prefer to operate between the attacks. (3) The fulminating form being of such rare occurrence and often manifesting symptoms by which it may be recognized before it is too late, and being so often fatal, whether medicinally or surgically treated, I am not influenced to treat all cases as though they were of this variety. (4) The patient is usually in a better condition for the operation after the acute symptoms have subsided. The toxæmia seems greater in the majority of cases during the first twenty-four or forty-eight hours, and the patient appears to suffer more from shock during this period. I believe chloroform or ether anæsthesia is more dangerous when the toxicity is great, and that these agents have some inhibitory action on the body cells, the serum of the blood, or the phagocytes. This deleterious action is especially objectionable at a time when nature's best efforts are required to combat the morbid phenomena. (5) The benefits of this delay, as it seems to me, with the adoption of correct medicinal treatment, are the increased flow of serum to the seat of inflammation and the formation of adhesions, in some cases, which shut off the general peritoneal cavity, and the lesser risk of auto-intoxication. I believe that the peritoneum, during operative procedure, is more likely to be infected before this immunizing or protective process has supervened. (6) The advantage hoped for when we would operate before the occurrence of perforation is quite often not realized in perforative appendicitis. In my experience, perforation takes place sooner than is ordinarily supposed."

The Action of the Vaginal Plug in Accidental Hemorrhage.—Dr. E. Hastings Tweedy (*British Medical Journal*, June 4th) says that accidental hemorrhage is one of the few complications in midwifery, concerning which a marked disagreement as regards treatment exists. To accomplish this little operation in a satisfactory manner many pieces of sterilized cotton wool are required, each the size of a small closed fist, which should be placed in a weak antiseptic solution. The patient is then brought to the edge of the bed and put on her left side. When the vagina and vulva have been asepticized and the bladder has been emptied, the pieces of cotton wool, from which the superfluous fluid has been squeezed, are taken, one by one, compressed into a small compass, and inserted without the aid of a speculum in such a manner that the entire cervix is surrounded by pledgets before the os is covered. Each piece is packed as tightly as possible, and when the vagina is filled to the utmost capacity down to the urethra a diaper is placed between the thighs, and the application of a tight abdominal binder completes the operation. He arrived at the following conclusions: (1) The vaginal tampon, when properly applied, is the most suitable treatment we possess for the worst forms of accidental hemorrhage. (2) It may be relied upon as sufficient in the majority of cases not amenable to other treatment. (3) It controls the circulation in the uterine arteries, acting in much the same manner as does a tourniquet. (4) It dilates the cervix partly by exercising a peripheral force on that structure, and partly by exciting uterine contractions. (5) These latter are induced not merely as a consequence of cervical dilatation but are chiefly attributable to the power the tampon possesses in bringing about an accumulation of carbonic gas in the uterus.

Antipyrin Exanthemata.—Dr. Lesser before the Dermatological Society of Berlin (*Medical Press and Circular*, April 6th) said that the antipyrin exanthemata were among the most extended of those due to drugs. The reason was that antipyrin was not only prescribed by the physician but was procured and used extensively by the laity. The characteristics were: (1) The appearance of only a few spots, the points of predilection being around the body openings; further, points liable to pressure; and lastly the effects upon the extremities, hands, and toes. (2) Their strong pigmentation and their long persistence. (3) Their occasional chilblain-like infiltration. (4) The outbreaks in the same spots every time antipyrin was taken. In addition to these, other parts might be attacked. There were violent burning and itching, which came on rapidly after the use of the drug.

Treatment of Inoperable Sarcoma by Coley's Fluid.—Dr. Mansell Moullin in a paper read before the Harveian Society (*British Medical Journal*, February 19th) offers the following conclusions, some of which may later require modification: (1) It could not be denied that there was a considerable number of cases in which sarcomata that had been given up as hopeless, often after repeated operations, had absolutely and entirely disappeared under this method of treatment. There was no other treatment, except infection with the streptococcus of erysipelas itself, of which this could be said. (2) Some of these cases had remained free from recurrence for upward of three years, the period which, in the case of the excision of the breast for scirrhus, was regarded by many operators as justifying the use of the term "cured." (3) Several of the cases in which sarcomata had disappeared after an attack of erysipelas had remained free for seven years and upward. (4) The fact that there might be a very few cases recorded in which sarcomata had disappeared, either spontaneously or after such diseases as acute specific fevers, had nothing to do with these conclusions. The statement that sarcomata did occasionally disappear was repeated with great regularity, but well-authenticated cases verified in the way in which Coley's had been verified were difficult to find. (5) These conclusions were not in any way invalidated by the fact that injections of the toxins were sometimes followed by the disappearance of other growths, such as lupus, keloid, syphilitic deposits, carcinomata, etc. It might make the disappearance of sarcomata more difficult to understand, but it in no way disproved it. (6) The proportion of cases of sarcomata that were cured by the injections of mixed toxins depended, among other things, upon the histological character of the growths. Spindle-celled sarcomata were by far the most successfully treated. This suggested the conclusion that the mixed toxins had a selective action, even if it was not specific. (7) The disappearance of sarcomata was not due to inflammation but to an intensely rapid form of fatty degeneration, comparable only to that which affected the hepatic cells in acute yellow atrophy of the liver. Inflammation and sloughing, when they did occur, were septic complications. (8) Degeneration and absorption might occur, whether the toxins were injected directly into the tumor or into some distant part of the body. In the former case the effect was more rapid, and the constitutional symptoms were severe. (9) The method was attended with a considerable degree of danger. It should, therefore, be adopted only in those cases in which there was no other remedy. The chief risk seemed to be from collapse and pyæmia. There must always be danger of the latter if there was a suppurating or sloughing sore. It might be argued that patients whose lives were threatened by a malignant growth would never be cured by

any remedy that did not involve some such degree of risk. (10) The cultures were of no use unless taken from a virulent case of erysipelas, or were made virulent by passing the streptococcus through rabbits. (11) The bacillus prodigiosus, in spite of the theoretical objections, had the effect of immensely increasing the reaction. (12) The effect was most striking in the case of rapidly growing sarcomata. Slowly growing ones seemed to have much more resistance. Probably this meant that masses of embryonic cells, with little organization, gave way to injurious influences more readily than those that were more closely knit together. (13) Patients often gained in weight and strength while under treatment. (14) Treatment should be continued until the growth had vanished, or until it had become so small that it could be removed. (15) If there was a recrudescence of the disease, it did not follow that the toxin would be so efficacious the second time as the first. Whether this was the result of tolerance being established could not be said. (16) Recurrence in other parts of the body might take place after many years. (17) The severity of the reaction was quite variable. Probably this depended upon the rapidity with which the injection was absorbed, rather than upon any cumulative action it might possess.

Syphilis as a Cause of Abortion.—Dr. J. A. Ouimet (*Medical Review*, vol. xxxvi., No. 15, page 267) concludes: (1) Syphilis is a powerful cause of abortion, the abortion being due to a lesion of the fœtus itself or its appendages. (2) It occurs mainly about the seventh month. The father, if alone syphilitic, can transmit the syphilis to the product of conception. The latter is more liable to occur the nearer the moment of conception is to the beginning of syphilis. (3) The mother may give birth to a syphilitic child while remaining free from syphilis. (4) When the father and mother are both syphilitic the child rarely escapes infection. (5) The mother, if syphilitic before pregnancy, is more liable to give birth to a healthy child the more ancient the syphilis. (6) The nearer the syphilis approaches the termination of pregnancy, the greater chance the child has to escape infection. (7) The child born of a syphilitic mother may come into the world presenting lesions manifestly syphilitic, or be born apparently healthy and become syphilitic only after some months or even years. Syphilis imparts no particular characteristic to the course of confinement. Mercurial treatment should be instituted at the beginning of pregnancy.

Preventive Treatment of Ophthalmia in Newborn Children.—The rules for the prevention of this ailment are as simple in their application as they are satisfactory in their results, and may be epitomized as follows: (1) If a pregnant woman be known to suffer from gonorrhœa, every attempt should be made to cure the complaint before parturition. (2) In case the ailment persists, the vagina and external parts should be irrigated during labor with some antiseptic fluid, and this should be repeated from time to time if the stage of propulsion be slow. (3) After the child is born, but before the cord is cut, any secretion lodged about the lashes or lids should be carefully wiped away with wool, moistened with perchloride lotion. (4) After the cord is severed one or two drops of a two-per-cent. solution of silver nitrate should be run into the baby's eyes, held open for the purpose. (5) Clean water must be used for washing the head and face, which must on no account be touched with that employed for the bathing of the body. (6) Secondary inoculations from the lochia, etc., must be avoided by the exercise of common sense and cleanliness.—Dr. Sidney Stephenson, *Medical Press and Circular*, June 8th.

Life Expectancy in Syphilitics.—Dr. James Nevins Hyde (*Medical Examiner*, April) says: "(1) Inherited syphilis is one of the most fatal of all disorders affecting the human race, and under the most favorable circumstances, irrespective of abortion and miscarriage, nearly ninety per cent. of infected children born living subsequently die. (2) Acquired infantile syphilis is very rare, is an exceedingly manageable disease, and is one in which probably a large proportion of infants survive. (3) Between eighty and ninety per cent. of all adult patients affected with acquired syphilis escape its gummatous complications. (4) The percentage of persons affected with gummatous syphilis who perish is not known, but one may doubt if it exceeds two per cent. of the ten to fifteen per cent. of those who suffer from gummatous complications. (5) The expectancy of life is probably affected by coincidence of syphilis with other diseases, and the prospect that the patient with acquired syphilis will ever suffer with either struma, tuberculosis, or cancer is exceedingly small. (6) The natural evolution of acquired syphilis in untreated cases in the adult is not in the direction of a lethal issue, but rather in the line of physical degeneration and grave complications due to involvement of the nervous system and of the bone, without affecting organs essential to the continuance of life. (7) It is unfair to charge an extra risk for the insurance of syphilitic applicants otherwise in sound health, and insurable, as any assumed unfavorable prospects due to the fact of infection are more than counterbalanced by the extreme improbability of death from either tuberculosis or cancer. (8) If what precedes has a fair foundation in fact, it follows that the syphilitic applicant for life insurance should be examined with a view not so much to his syphilitic history as to his condition with relation to all other items making up a satisfactory risk. In other words, if he has a good family history, a sound constitution, excellent habits, and has reached, but not passed, a satisfactory age, his expectancy of life is probably that of other individuals in similar conditions, without added risk in consequence of his specific disorder."

Senile Uterine Catarrh.—Dr. J. Holliday Croom, physician and clinical lecturer on diseases of women, Royal Infirmary, Edinburgh (*The Edinburgh Medical Journal*, April) says: "In regard to the differential diagnosis between primary corporeal cancer and senile uterine catarrh, the following points are worthy of consideration: First and foremost in most cases of primary fundal cancer, periodic and severe pain is an early and prominent symptom; whereas in senile uterine catarrh the pain is irregular and colicky, or, if not, it is slight and constant. Secondly, in cancer, fetid discharge, at least in the early stages, is unusual, because the os is closed and the face of the cancer is protected from external influences; whereas in catarrh, fetid discharge is a prominent and early symptom. Thirdly, local examination in cancer finds the uterus distinctly enlarged and sensitive, and it early becomes heavy and fixed; whereas in the simpler condition the uterus is either normal or only slightly enlarged, and remains freely movable throughout. Lastly, dilatation and local exploration reveal the presence of the neoplasm in the one case and the absence of all irregularity in the other."

Infective Gastro-Enteritis.—

℞ Tr. iodi..... 15–18 gtt.
Aquæ destil..... 150 gm.
Syr. simplicis..... 20 gm.
M. S. Teaspoonful every one or two hours.

THE RETURNED TROPICAL INVALID.

IT is hardly an exaggeration to say that the members of the fifth army corps, returned from Santiago, have suffered more from tropical diseases at Montauk Point than they did while in Cuba. Many deaths from malaria and dysentery have occurred among them, even among those who were thought upon their arrival at Camp Wikoff to be convalescent, and others, supposed to have entirely recovered, have been brought to bed again with recurring malarial fever. In the majority of cases these relapses have resulted from over-exertion and imprudence committed through ignorance by men who thought themselves safe once they were in northern latitudes. There is no greater error, however, than to assume that one is safe from the consequences of tropical disease as soon as he has come into a temperate climate, and nothing is more dangerous than to presume upon this assumption.

In an article in *Treatment*, of August 11, 1898, Dr. James Cantlie makes some practical suggestions concerning the treatment of the tropical invalid upon his return to Great Britain. The author's remarks are directed chiefly to the management of the chronic invalid, one who has been a resident of the tropics for a long period, yet they are applicable also in great part to the sufferer from acute malaria, especially that of malignant form such as incapacitated our men about Santiago. The one marked and lasting feature, he says, which is imposed upon the physique by a residence of any length in a tropical country is anæmia, not a mere functional anæmia, but a true organic oligocythæmia. The causes of this blood poverty are numerous, but probably the most potent is malaria, whether the affection be mild in form and long continued or intense but brief. Not only is there a diminished number of corpuscles available for oxygen carrying, but there is also a loss of power to regenerate the normal and pathological waste.

One of the main indications, therefore, in the treatment of one returning from the tropics is to combat the anæmic condition. In view of this, Dr. Cantlie says, a large city is the last place such a person ought to take up his abode in on first coming home, for it does not supply him with the one thing needful, namely, oxygen. Even the permanent residents of any large city find it quite impossible, as a rule, to maintain good health without a change. But although there is a plentiful supply of pure oxygen-laden air in most parts of the country, the choice of a place in which the tropical invalid may recuperate is by no means a matter of indifference. Most city physicians, certainly those in large towns away from the coast, would think first of the seashore as an ideal place for recuperation. This, the writer says, may be excellent advice for the inland town dweller, but it is not necessarily so for the returned tropical sojourner, and, as a matter of fact, experience has proven that the tropically anæmic person is not benefited by residence at the seaside. The air at that low level may seem fresh and possessed of tonic properties, but to the class of patients under discussion it is really relaxing and brings neither appetite, nor sleep, nor muscular vigor. Mountain air is what such persons need and in which they thrive. The elevation need not be great, and probably one thousand feet, or even less, would be sufficient. The wisdom of Dr. Cantlie's advice has been shown in the case of a number of the soldiers back from Cuba, who suffered severely at Montauk, pure and tonic as is the air there, but "picked up" almost immediately upon going up to the Adirondacks or into Sullivan County on furlough.

Another point in the advice given to the tropical invalid by the writer of this interesting paper is to avoid crowded rooms. "A visit to the theatre is generally followed by a restless night and a depressed physical and mental state on the following day. Dinner parties—to a succession of which one is usually subjected when one returns from a lengthy stay abroad—are likewise detrimental, not necessarily from the indulgence at table, but more certainly from the close air of the dining-room. Attendance at church, especially evening services in ill-ventilated churches—and all churches are ill ventilated—is accompanied and followed by consequences which soon cause one to dread the ordeal."

Finally, a word of warning is given against exposure to the sun. One who has suffered under the vertical rays of the sun in the tropics is tempted to regard the heat of the sun in 40° and 50° north latitude as something to be despised. But experience shows that this scorn is ill inspired, and exposure to the direct rays of the sun, even on a cool day, is often sufficient to provoke a chill and a sharp rise of the body temperature. The same effect is apt to be produced by fatigue or by a wetting. The combined effect of fatigue and exposure to the sun was shown recently in this city, when numbers of the members of the seventy-first regiment were prostrated with a return of fever after their march up Broadway, and the same result would doubtless have followed the suggested review in this city of all the troops that had served in Cuba, had not wiser counsels prevailed. In short, one who has suffered from tropical diseases after a long or a short residence in a hot climate is an invalid, and must be treated as such, and must not be allowed to act as a well man because the first breath of cool air has stimulated him and given him a false sense of vigor.

Lieut.-Col. Nicholas Senn, surgeon of volunteers, was honorably discharged on September 21st, his services in the United States army being no longer required.

THE PREVENTION OF CANCER.

According to the reports of the registrar-general, the mortality from cancer in England and Wales is progressively increasing out of all proportion to the increase in population, and with a rapidity that may well arrest the attention of sanitarians. A study of a table compiled from these reports and published by Mr. W. Roger Williams in *The Lancet* of August 20, 1898, shows us that in 1840 cancer caused 2,786 deaths, the proportion being 1 in 5,646 of the total population and 1 in 129 of the total mortality, or 177 per million living; in 1896 the deaths due to it numbered 23,521, or 1 in 1,306 of the total population and 1 in 22 of the total mortality, or 764 per million living. Thus the proportionate mortality from cancer now is four and a half times greater than it was half a century ago.

It is impossible to explain this remarkable increase in the mortality from cancer otherwise than by an increase in the prevalence of the disease. The assumption that the increase is only apparent and is due to improved methods of diagnosis is untenable, for it is probable that the reverse is nearer the truth and that many cases formerly diagnosed as cancer are now classed under other heads. The attempt to explain this increasing mortality as due to the average age of the population having advanced and the consequent greater liability to cancer will also not bear critical examination, Mr. Williams shows, for the saving of life in modern times has been mainly confined to early years. The number of deaths among men over thirty-five years and women over forty-five years has remained stationary or increased, while the number of persons who attain old age has decreased.

In respect of this immense increase in mortality cancer is unique, for nothing at all approaching it is furnished by the statistics of any other disease, and yet no effect appears to have been produced on the medical profession or the general public by these startling figures of the registrar-general's reports. Concerted efforts are being made to stay the progress of tuberculosis, while the warning of the cancer mortality is neglected. Yet, if the disproportionate increase in deaths from malignant disease continues, cancer will soon be as lethal as typhoid fever, smallpox, and tuberculosis combined. In the face of these statistics it behooves sanitarians to investigate with great care the conditions which favor the development of cancer, whether these be personal or regional, dietetic or microbic, for it is only by the avoidance of the main etiological factors that a decrease in the prevalence of cancer can be attained. In this respect Mr. Williams is very optimistic, and he unhesitatingly expresses the belief that there need be no more difficulty in mitigating the prevalence of cancer—and perhaps even in eventually extinguishing the disease altogether—than there is in the case of the maladies mentioned above.

This hopeful view is, of course, based upon a positive theory as to the origin of cancer, the tendency to which he believes may be increased by unsuitable modes of living, and *vice versa*. Concerning the etiology he says: "Such influences as are comprised under the terms alimentation and domestication seem to me to be of paramount importance. Probably no single factor is more potent in determining the outbreak of cancer in the predisposed than high feeding. There can be no doubt that the greed for food manifested by modern communities is altogether out of proportion to their present requirements. Many indications point to the gluttonous consumption of meat, which is such a characteristic feature of this age, as likely to be especially harmful in this respect. Statistics show that the consumption of meat has for many years been increasing by leaps and bounds, till it has now reached the amazing total of one hundred and thirty-one pounds per head per year, which is more than double what it was half a century ago, when the conditions of life were more compatible with high feeding. When excessive quantities of such highly stimulating forms of nutriment are ingested by persons whose cellular metabolism is defective, it seems probable that there may thus be excited in those parts of the body where vital processes are still active such excessive and disorderly cellular proliferation as may eventuate in cancer. No doubt other factors coöperate, and among these I should be especially inclined to name deficient exercise and probably, also, deficiency in fresh vegetable food."

This is interesting, as guesses after truth always are, but something more solid than a coincidence is needed as a basis for sound theorizing. The consumption of alcohol has increased of late, as well as that of meat, and we might therefore with equal justice attribute cancer to indulgence in alcoholic beverages. As regards physical inactivity, also, we question whether in this age of bicycling and out-door sports people take less exercise than formerly. It would be interesting also to learn whether professed vegetarians ever suffer from carcinoma.

THE RESPONSIBILITY OF THE ARMY MEDICAL DEPARTMENT.

Surgeon-General Sternberg has published in the daily press a statement disclaiming on behalf of himself and the medical department all responsibility for the sufferings of the sick and wounded soldiers on the transports, in camp, and on the battlefield. He says that it is quite impossible for him personally to administer or even to supervise the medical administration of armies in the field. For this purpose there is a chief surgeon for each military department, for each army corps, for each division, and for each brigade. These chief surgeons are directly responsible to the commanding generals of the troops with which they are serving, and the surgeon-general has no direct authority over them. He thinks it is absurd to hold him responsible for the conduct of five hundred or more volunteer regimental surgeons and contract doctors, most of them without any previous military experience, or even for that of the six hundred acting assistant surgeons, who were employed without having been subjected to a preliminary examination. "In

short," he says, "the surgeon-general of the army is not personally responsible for the neglect or incompetency of medical officers, whether regular or volunteer."

The responsibilities which he admits are the following: As chief of the medical department he recommends the assignment of medical officers to duty as chief surgeons of army corps and of military departments, and these chief surgeons are responsible for the proper administration of medical affairs in the commands to which they are attached. The surgeon-general has direct charge of all general hospitals, of the medical supply depots, of hospital ships, of the army medical museum, of the enlistment and distribution of members of the hospital corps, of disbursements for artificial limbs, of the payment of all bills against the medical department of the army, etc. He also is responsible for the purchase and issue of medical supplies for the army, the surgeons on duty with troops being of course expected to make timely requisition for supplies, since the surgeon-general cannot be expected to foresee and provide for all emergencies that may cause an unusual consumption of certain drugs.

Concerning the hospital trains, Dr. Sternberg says that the trains which are going from one part of the country to another with troops, and which frequently are reported as carrying sick men unfit to travel, are not under his control. As a rule, he knows nothing of their departure or arrival, and cannot be expected to have supervision of the sick, "who are placed upon these trains by regimental surgeons, often very injudiciously, and no doubt in response to the urgent solicitation of the men, who wish to go home with the regiments that are to be mustered out." The surgeon-general himself has at his disposal but one hospital train, and this is made up of tourist sleepers, thoroughly equipped for transporting sick men.

He likewise disclaims all responsibility whatever for the hideous condition of many of the transports which brought the sick and convalescent soldiers from Santiago. These transports, he says, were not under his control, and, as a rule, he had no information with reference to their departure or the preparations made for the care of the sick to go upon them. These preparations should be made under the direction of the chief surgeon at the point of departure; but the transports themselves are under the control of the quartermaster's department. The only ships which have been fitted up expressly for transporting sick soldiers are the hospital ships *Relief* and *Missouri*. These are under the immediate control of the surgeon-general, and are thoroughly equipped for the work for which they are intended.

With responsibility for the health and the life of our troops so widely distributed as to sit with imponderable lightness upon any one surgeon, we can little wonder th t the misery was so great. It speaks volumes for the devotion and humanity of the individual members of the medical corps that so much was done for the sick and wounded as was done, since there was apparently no head to direct and to supervise. The duties of the surgeon-general, as authorized in the statement to which we have referred, seem to be such as could be performed by any person of ordinary ability, and to call for little or no special medical knowledge. It must be very trying to the nominal head of the medical department of the army to have so little authority over his subordinates, and we are not surprised that in his helplessness to correct abuses he disclaims responsibility for them.

THE OMNIPRESENT MICROBE.

The bacteriologist is becoming as grasping as the surgeon in appropriating as his own all manner of diseases and distempers within and without the human frame. Rheumatism and cancer, bald heads and senility, have been placed in the credit column of the microbe's ledger, and now comes a Montreal physician, Dr. Adami, blowing away the alcoholic theory of hobnailed liver and introducing a minute micro-organism as the active agent in the production of the lesion. He has examined a number of cirrhotic livers and found in them certain microbes, which, however, on account of their minute size and refractoriness to the usual staining methods, he is unable to describe satisfactorily. Many of the forms, he says, resemble closely minute editions of the gonococcus. They also vary to some extent in size, though this, he thinks, may be a matter of imperfect staining or an evidence of polymorphism of the germ. He is, on the whole, inclined to regard the organism as a bacillus rather than as a diplococcus.

Dr. Adami wisely refrains at present from putting down portal cirrhosis as a frankly microbic disease, but he goes so far as to say that "in a certain number of cases, at least, of hobnailed liver, there is present, more especially in the liver and the abdominal lymph glands, a minute micro-organism resembling closely that found pathogenic in the infective cirrhosis of cattle; a form which is present most frequently as a minute micrococcus, but sometimes has a more bacillary appearance, and which is thus to some extent polymorphous."

We trust the scientists of the Woman's Christian Temperance Union will resist this bold attempt to do away with a forcible argument against alcoholic indulgence. In the words of a worthy Episcopal clergyman of this city, who refused to sanction the circumcision for adherent prepuce of a boy of one of his parishioners, we cannot but regard this investigation of Dr. Adami as "subversive of the principles of the Christian religion," and in the interest of morality it is to be hoped that the author's staining methods will not be improved.

Humanity of a Spanish Surgeon. — During the infantry skirmish following an attack on the landing party from the *Gloucester* at Guanica, Porto Rico, one of the volunteer soldiers, outrunning his comrades, advanced far ahead of his line. When he had nearly reached the Spanish position, he was overcome by the heat and fell in a semiconscious state. A Spanish doctor and two hospital-corps men rushed to his aid with a stretcher, administered the necessary restoratives, and had him conveyed at once within the American lines.

News of the Week.

New Doctors in Pennsylvania. — Examinations of candidates for license to practise medicine in the State were recently held in Pittsburg and Philadelphia. There were 317 candidates, 63 in Pittsburg and 254 in Philadelphia, of whom 49 were rejected. The winter examinations will be held in Philadelphia, December 12–15, 1898.

Cholera is epidemic in Madras and is steadily increasing in its prevalence. During the week ending August 19th, ninety-one deaths and about two hundred cases were reported.

Vaccination in France.—At the congress held at Nantes M. Brouardel proposed a resolution, which was unanimously adopted, to the effect that compulsory vaccination should be extended to Tunis. In France vaccination is enforced by strict regulations, which do not meet with any opposition from the public. All persons seeking employment of any kind are required to produce a certificate of vaccination, and all soldiers are revaccinated on joining their regiments. The Academy of Medicine also awards every year a considerable number of prizes and medals to the medical practitioners who have performed the most vaccinations and revaccinations. In fact, vaccination is taken quite as a matter of course in France. Under these circumstances no one looked for a campaign against vaccination undertaken by the celebrated anti-Jewish journalist, Edouard Drumont, a campaign undertaken in the name of individual liberty, and, which is still more strange, in the name of hygiene as understood by M. Drumont. In an article which has produced some sensation and caused astonishment, rather than made converts, he declares that small-pox is not a disease but a natural process, in the course of which the organism spontaneously throws off morbid products which it contained; in his opinion vaccination is the only cause of racial degeneration and of the increase of new diseases which were formerly unknown. On this ground Jenner must be regarded as a scourge of humanity, although it is admitted that he possessed the merits of being an excellent father and a naturalist who carefully studied the habits of the cuckoo.—*The Lancet.*

Abortion in Canada.—A discussion was recently held in a Montreal Anglican Church convention upon the low birth rate in Ontario, and the cause therefor was asserted to be the wide prevalence of criminal abortion and of the use of artificial means to prevent conception. The low birth rate may be due partly to the cause assigned by the ministers, but it is also associated with a very low marriage rate, which would seem to account for it in a measure.

Matches without Phosphorus.—The prize recently offered for the discovery of a means of making matches without the use of red phosphorus has greatly stimulated research, and it is reported that two chemists in Berlin have invented a match that can be ignited by friction on any surface and which is made without any phosphorus.

Dr. Dietrich Nasse, of Bergmann's klinik at the University of Berlin, lost his life last week in the Alps. He and another Berlin physician, Dr. Borchardt, with two guides, the four men roped together, were crossing the Piz Balne over a snow bridge, which gave way, and the leading guide and Dr. Nasse fell into a crevasse. The latter had the rope around his chest and hung in midair. A half-hour later, to relieve the intolerable strain, the guide cut the rope between himself and Dr. Nasse and disappeared into the depths. The other guide and Dr. Borchardt were then able to pull Nasse up, but he was dead. The guide who was ready to offer his life for his employer was but slightly injured and was able to scramble out unassisted from the crevasse into which he had fallen.

The Naval Medical Service.—For the first time in many years there is no vacancy in the medical staff of the navy, the corps being now up to the authorized commissioned strength. This is, of course, due to the war, and if the unjust discrimination against the surgeons in the navy can now be finally done away with, there will be no difficulty in filling promptly all vacancies that may occur in the future.

The Water Famine in London.—Owing to the drought and unprecedented hot weather, the scarcity of water in East London, referred to by our London correspondent, has been growing more and more alarming. The population dependent upon that particular water company numbers about two millions, to whom water is supplied for three or four hours only out of the twenty-four. In its issue of September 17th, *The Lancet* says that "if the present abnormal condition of meteorological things continues the consequences may be most serious. The rivers are depleted to the utmost. The drains are not adequately flushed and there is little flow in the upper reaches of the city to carry off the daily discharge of sewage." The only security for Londoners against a repetition of this most dangerous shortage of water, our contemporary holds, is to build an aqueduct to the watershed of Wales, where the supply is literally inexhaustible. The length of the required aqueduct would be about one hundred miles.

Death from Laughter.—A man died in New Orleans a few days ago as a result of laughter. He was at the theatre, and began laughing so heartily that he lost control of himself and fell to the floor, dying in syncope. He had suffered for some time from valvular heart disease.

The Increase of Suicides in Italy in 1897, compared with the average of the ten preceding years, was over 50 per cent. The total number of suicides for that year was 1,997, which corresponds to a mortality of 6.41 for every 100,000 inhabitants. In this total 1,401 were men and 596 were women. Married persons numbered 810, unmarried 949, widowers 177, and widows 61. The greater number of suicides took place in the spring and summer, being respectively 614 and 572. The majority of suicides were reported from the provinces where education is most widely diffused and the ratio of illiteracy lowest.

Osteopathy.—A correspondent inquires concerning the essence and the foundation of osteopathy. We confess to a somewhat hazy idea of the principles upon which the "system" is based, and turn therefore to the following lucid explanation given by A. T. Still, the founder of osteopathy. If our correspondent is not satisfied with this exegesis, we cannot help him further: "I feel to answer through the *Journal of Osteopathy* questions that are asked by thousands of persons annually. And as time adds days and years the number of persons who ask those questions have multiplied to such greatness in numbers that is absolutely impossible to find the time to answer them in detail. And I am not sure that I can answer all of them through the *Journal*, but will try and so arrange that a few of the most common ones will be answered as best I can. By my method of reasoning I arrive at the conclusion that man was, after receiving his form, like unto the world on which he dwells, and that in his body could be found all the mineral, vegetable, and animal substances that could be found in the beast of the field, the fowls of the air, fishes of the sea both great and small, in short, all that was contained in this and all other planets and beings, from the throne of God (Himself included), to the lowest form of animated beings; that in the human being all attributes of mental and physical were represented in kind. With this conclusion I proceeded and did obtain what I have proclaimed and proven to be truths universal in kind and action, submitting to and being governed by one common law. I reasoned that all effects as are shown in disease with the result of the productions of the truths of the one great common law, mind and motion expressing themselves through matter. Motion is an effect of life with its powers. Disease in any form or presentation was another effect. Conception of beings, diseases, and worlds, were the biogenic answer of the wombs of nature either large or small, believing while I was in the chambers of sober and intelligent nature where honest reason only can dwell, that it was safe to follow the teachings of that principle that made no mistakes that I could detect. . . . The world's systems of cures by drugs are now and always have been based on three principles, namely: opiates, purgatives, and stimulants. And the difference there is in the schools of medicine are about all told in the quantities to be given. All give deadly poisons but try to get the same results. Allopathy starts the ball to rolling by big pills, eclecticism the same, but claims that vegetable medicines are better than mineral preparations. Then the homœopath closes by pills of less size, and if they fail he drives morphine under the skin and spills it in the fascia, which carries the opium to the brain and produces effects by paralyzing sensation. And on these three principles all depend."

Hospital Ships for French Fisherman.—The *British Medical Journal* gives an account of the misfortunes of the Société des Œuvres de Mer, a society which was founded in 1895 for the purpose of giving aid to the French fishermen off the shores of Iceland and Newfoundland. In less than two years the pioneer hospital ship, a sailing vessel admirably equipped and capable of accommodating thirty patients, was dispatched to Newfoundland; but the ship, named the *St. Pierre*, was totally lost in a fog, and her sister ship, the *St. Paul*, which left for Iceland soon afterward, was cast upon the coast of that island during a gale. Eventually the *St. Paul* was redeemed, and she is still afloat; but the society's ill luck was not yet exhausted, for its third hospital ship, the *St. Pierre* No. 2, had no sooner arrived off the Bank than she collided with a smack, receiving serious injury. In spite of these misfortunes, however, the society is still at work—in the words of Dr. Bonnafy, is "*au vent de sa bouée*," a nautical phrase, which may be freely translated as running before the wind. In addition to its work afloat, the society has also established *maisons de famille* on shore for the fishermen, many of whom are no more than boys. In 1896 the daily attendance at these refuges was one hundred and twenty-two; in 1897 it was one hundred and ninety-eight.

Obituary Notes.—Dr. George W. Lindheim, assistant surgeon of the eighth New York volunteer regiment, died at his home in this city, on September 16th, of typhoid fever. He was twenty-seven years old, and was a graduate of the College of Physicians and Surgeons of this city. He recently returned to New York in charge of a hospital train bringing sick members of the eighth regiment from Chickamauga. While passing through Cleveland he was pestered by some newspaper reporters and physicians, who insisted upon his sending to hospital there some of his sickest charges. They said the men would not live long enough to reach New York and threatened to "roast" Dr. Lindheim if he did not yield to their demands. He said he had been instructed to bring the men to New York and intended to do so. They all arrived alive and none, except Dr. Lindheim himself, has yet died. He was taken ill two days after the arrival here, and in his delirium was constantly rehearsing the criticism to which he had been subjected from reporters in Cleveland and elsewhere along the route, and also from some of his own men who complained that he was starving them because he would not allow the convalescents from typhoid fever to eat themselves into a relapse.—Dr. Joseph Kufner, of this city, died on September 14th. He was born in Germany sixty years ago, and studied at Munich and Vienna. After coming to this country he took a course in medicine at the Bellevue Hospital Medical College, whence he was graduated in 1882.—Dr. William Lindsley Mussey died suddenly last week in Paris. He had studied at Yale and Johns Hopkins University and was graduated from the Miami Medical College in 1887. He had been studying during the past two years at Vienna and Paris. — Dr. Henry Otto Clauss, of New York, killed himself with a pistol on September 19th. He was born in Germany seventy-three years ago and came to this country when quite young. He was a graduate of the Long Island Hospital Medical College in the class of 1865. He leaves a son, a physician.—Dr. Philip Arthur Malleson,

of New York, died at his home, on September 19th, of appendicitis. He was born at Glens Falls, N. Y., in 1859, and was graduated from the College of Physicians and Surgeons in this city in 1884. He was one of the founders of the Harlem Medical Association.

The Medical Directory of the City of New York.—Candor compels us to say that the medical directory published under the auspices of the Medical Society of the County of New York, a new edition of which has recently appeared, is a poor affair. In no sense can it be said to fill the place left vacant by the cessation of publication of the "Medical Register." The lists of physicians are sadly incomplete, the necessity of referring to two lists to find one name in New York city is exasperating, and the lack of information concerning any physician who has the misfortune not to be a member of the county society still further impairs the usefulness of the work.

Vaccination in England.—The average fee for a vaccination in England is, according to the *Medical Times*, half-a-crown or sixty cents. This involves two visits, the filling up of a certificate, and the cost of the vaccine.

Typhoid Fever Spread by Flies.—The commission, consisting of Drs. Lee, Vaughan, and Shakespeare, which was appointed to inquire into the cause of the camp epidemics of typhoid fever, has concluded its investigations. The camps at Chickamauga, Huntsville, Fernandina, and Jacksonville were inspected. It was found that the typhoid fever in each instance was brought by the volunteers from their State camps. The water supply was in most places good and was not responsible for the spread of the fever. This was effected, in the opinion of the members of the commission, by the flies which swarmed in all the camps and devoted their attentions impartially and alternately to the fæcal matters in the open and not disinfected sinks and to the hardtack and "sow belly" of the troops.

Street-Car Surgeons Recognized.—At the meeting of the International Association of Railway Surgeons, held recently at Toronto, the executive committee adopted a resolution declaring that surgeons of street-car and elevated railroads are eligible for membership in the association.

The Health of the Marines.—The health statistics of the marine corps on duty for many weeks in Cuba would seem to show, what every one with experience knows, that it is possible with proper care to keep troops in good health in the tropics, for a certain period at least. The marines landed at Guantanamo, only a few miles distant from Santiago, occupied the same soil, fought in trenches, and endured almost if not quite as many hardships as the soldiers, and were there for a longer time. Their health was, however, carefully watched, and the precautions taken were successful in preventing disease, for not a man was lost through disease, and the percentage of sickness was at no time above two and one-half. The marines went to Cuba with tents and other equipage. They had flooring for the tents, which could be put together with screws. After they had started, their canvas uniforms were sent to them. They were all trained men, and they observed without complaint the sanitary regulations prescribed by the officers. The latter carefully watched the diet, the drinking-water, and everything that conduced to the comfort and welfare of the men in their charge. When the tents were pitched, the floors were put together and placed on rocks, a rock at each of the four corners, raising the floor slightly from the ground. This prevented the soldiers from coming into personal contact with the soil, and permitted proper drainage and ventilation of the tents.

Medical College Consolidation.—There is a growing tendency, and one that should be encouraged, throughout the country to a union of two or more weakly medical colleges in any one city and the formation from them of one strong institution. Nashville, Buffalo, and New York have led in this reform (though the latter has gained nothing in the way of reducing the number of schools, merely preventing an increase), and now there is talk of consolidation in Columbus, Ohio. The *Columbus Medical Journal* says that a proposition had been made looking to a union of the Ohio Medical University and Starling Medical College as the medical department of the Ohio State University. There are some objections, sentimental and financial, urged against the proposed foundation of a medical department of the State University out of the remains of the two existent schools, but the advantages are patent and should outweigh all objections to the scheme.

The Sick at Santiago.—On September 20th there were 1,187 sick among the United States troops in and about Santiago, and of these 679 were reported to have "fever." What is meant by this term is not stated, but it is probably intended to cover typhoid fever, yellow fever, and malaria, since we find these three specifically mentioned among the causes of deaths.

Yellow Fever in the South.—Isolated cases of yellow fever have been reported in New Orleans, and in Jackson, Oxford, and other places in Mississippi. The State board of health has adopted an ordinance forbidding steamboats and other craft clearing from New Orleans to land at any point in Mississippi, until the Marine Hospital service places inspectors on all boats. Surgeon-General Wyman, of the Marine Hospital service, has completed a system for the inspection of trains on all railroads in that part of Mississippi which is infected with yellow fever. Inspectors have already been placed upon nearly all the roads, and will soon be placed on all. The system has been established for the purpose of checking the spread of fever so far as practicable, and it is the purpose of the bureau to make it as effective as possible. Passed Assistant Surgeon Stimpson is in charge of the service.

The Smoke Nuisance.—So many complaints have been made this summer of establishments burning soft coal, that the board of health has divided the city into twenty-seven "smoke" districts, each of which will have an inspector to report as to smoke nuisances.

Clinical Department.

BROMIDE OF POTASSIUM FOR THE MORPHINE HABIT.

By C. H. HUMPHREYS, M.D.,
DAYTON, OHIO.

I was asked recently to see a physician who had unfortunately acquired the morphine habit, and who, after many ineffectual efforts to stop the use of the drug by "tapering off," saw an account by Dr. MacLeod in the *British Medical Journal*, of the cure of the morphine habit by bromism, and determined to give it a trial. He had taken about three ounces of the salt when his family grew alarmed at the mental disturbances produced, and requested me to see him. I found him deeply under the influence of the bromide, and, learning the true state of affairs, had him removed to the hospital, the better to conduct the treatment. Not being satisfied with his statement that he had been taking on an average twelve grains of morphine a day, I cut the injection down to half a grain three or four times a day, and then gradually reduced it to one-fourth of a grain twice daily, until on the fifteenth day of his hospital treatment he, of his own accord, refused further injections of the morphine, although it entailed considerable suffering. The cessation of the drug was followed by the usual digestive and nervous disturbances for several days. At the end of the third week the patient returned to his practice, freed from all desire for morphine, he firmly declares.

As a result of the bromism and the withdrawal of the morphine there were great muscular relaxation and general lassitude, which were relieved by hypodermic injections of strychnine.

The patient is of the opinion that the morphine should have been entirely withdrawn while he was under the full effect of the bromide, as the continuance of it, even in small doses, after the effect of the bromide had passed off, only fed the old flame and in a measure converted the treatment into the gradual-withdrawal plan, with its attendant suffering.

A SPLINT FOR FRACTURE OF THE FEMUR IN THE INFANT.

By PATRICK J. TIMMINS, M.D.,
BOSTON, MASS.

The most skilful accoucheur may meet cases of breech presentation, in which a fracture of the infant femur, or, more correctly, a separation at the epiphysis, is unavoidable, if, indeed, it be not the *sine qua non* of delivery *per vias naturales*. I can place three such cases to my credit in the space of fifteen years. All three patients are alive and able to kick. I had much difficulty in treating the first two, for want of acquaintance with a suitable splint. The last was a real pleasure to handle, because of an appliance which I think worthy of introducing to my professional brethren. I cannot claim to be the originator of this splint; I was merely the one that gave it its present form. The seed was sown by my friend, Dr. Francis E. Cane, of Brooklyn, N. Y., late of Boston.

The child, having been carefully washed, should be thoroughly rubbed all over with alcohol, to harden the skin. Then the physician should select a fairly stiff sheet of tin, a little wider than the child's body, so that it can be dished up about an inch at the sides, and long enough to extend from the shoulders to the heels. A piece is cut out of it from opposite the coccyx to the heels, so as to give on either side a strip for each leg. The operator must see that enough room is made in this cutting for the easy application of a pad of gauze to receive the fæces and urine. The splint is to be well padded with sheet wool and the padding liberally dusted with powdered boric acid. The physician then secures with two wide straps of adhesive bandage the wide part to the body, one of the straps being placed around the chest, the other about the pelvis. The strip of splint which is to secure the broken leg is next to be flexed with the thigh, and then bent back at the knee, leaving the femur portion long enough to serve for a fulcrum, on which may be extended into place the separated bone.

Counter-extension is secured by the already fixed pelvis. The femur and leg are strapped, as needed, to the spint. The sound leg is done up in the same way, and then the body and both legs are bandaged as far as the feet.

The patient is now secured, as it were, in a chair, and can be carried about or laid to rest with perfect ease and security. By using a piece of rubber sheeting or oiled silk to cover the edge of the padding about the anus, cleanliness may be insured. To take the measure for the splint, a sheet of paper is to be placed under the infant, laid on its back on a table, and a stroke of a pencil around the body and legs will mark a pattern, which is to be cut out and pasted on the sheet of tin. A pair of tinsmith's shears will do the rest.

The fracture I treated in this manner was left undisturbed for three weeks. The result was excellent. The ease with which a child so put up can be handled by mother or nurse will be found not the least advantageous feature of the treatment.

GREEN-STICK FRACTURE OF BOTH BONES OF THE FOREARM IN A CHILD EIGHTEEN MONTHS OLD.

By GEORGE H. WILLIAMS, M.D., M.R.C.S. Eng., L.R.C.P. Edin.
FISHKILL-ON-HUDSON, N. Y.

On May 21, 1898, I saw E. B—— for the first time; the patient was eighteen months old. The end of April, or about four weeks previously, the child had fallen out of a low swing, striking on the ball of each wrist; and although he cried very hard he was soon comforted, and the parents thought no more of the accident until two or three weeks later, when the arms seemed bowed and increasing in deformity. It was four weeks after the accident when I was first consulted.

On examination, the left arm showed a green-stick fracture of both radius and ulna, the greater deformity being backward and about the middle of the bone; the ulna was also fractured at the same level, but did not show so much deformity. The right arm was less deformed, but the fracture in the lower third was of the green-stick variety also and the bowing was also backward. The seat of fracture showed callus, especially about both radii, less about the ulnæ.

On May 29th, I examined both arms at my office with the *x*-ray, and there verified the previous diagnosis. On June 5th, the child was put under chloroform and the left arm, the one with the greater deformity, was refractured and put up in wooden splints. On June 12th the wooden splints were removed, and as the arm seemed in good shape a few turns of flannel bandage were applied, including the hand and extending to the elbow, and over this a silicate-of-sodium dressing; a ten-yard gauze bandage, two inches wide, being rolled through the solution and quickly and snugly bandaged over the flannel. The little fellow was now put under chloroform again, and the right arm was refractured and put up in wooden splints. On June 17th the right arm was taken out of the

splints and permanently put up, as the left had been, in silicate-of-sodium solution, prepared and applied as before. On June 19th both arms were again examined by the *x*-ray and found in good position.

I must acknowledge that I was surprised to find how plainly the bones could be seen through this fairly thick casing. It has been argued that one objection to a permanent dressing after fracture is the inability to watch the progress of the case, but it will be seen that the above-described dressing permits us to examine the position and condition of the fracture, and still gives us even a lighter dressing than splints afford, which in the case of fracture of a child's arm is an important item.

It may be that others have called attention to the above, but I have never seen it anywhere, and thought this report might consequently be of interest.

June 20, 1898.

REPORT OF A LARGE OVARIAN CYST SUCCESSFULLY REMOVED.

By J. SHELTON HORSLEY, M.D.,

EL PASO, TEX.

During the first few years after the general introduction of antisepsis into surgery, the removal of unusually large ovarian cysts was a matter of common occurrence, for in the preantiseptic era the danger of sepsis from any surgical operation—particularly from one involving a serous cavity—was so great that ovariotomy was considered by a number of prominent surgeons of those times an unjustifiable procedure. As a consequence this operation was performed very infrequently, and then only by the very bold. So, ordinarily, the growth of an ovarian cyst was, with the exception of occasional tappings, uninterrupted till death ended the patient's sufferings. But now, with our modern aseptic technique and comparative immunity from infection, the operation has been shorn of its most dreaded dangers, and is so universally performed that it is rare to see a cyst that the surgeons have permitted to attain a weight of even a few pounds.

In view of this fact, the following case may be interesting: Mrs. E. L——, Mexican, aged thirty-four years. Previous health before development of tumor good; family history negative. No children; one miscarriage about a year after marriage. The patient has been married seventeen years. Menstrual flow regular. Soon after her miscarriage she noticed a "swelling" in the abdomen. There were some pains and aches in the back, but nothing of consequence. The swelling gradually increased, and after a few years there was complete procidentia uteri. An examination when I first saw her (June, 1898) showed the classical symptoms of an ovarian cyst—fluctuation, dulness on percussion in front when lying down and tympanites on the sides, and the characteristic globular appearance of the abdomen. The navel was almost obliterated by the excessive tension on the abdominal walls. As fluctuation was the same in all directions, and as the contour of the cyst appeared globular and regular, a diagnosis of unilocular ovarian cyst was made. Her emaciated condition and the peculiar facial expression, so often remarked upon in patients with this disease, are well shown in the accompanying cut.

On June 10, 1898, I operated on this patient at Hôtel Dieu, with the assistance of Drs. Turner and Wright, the former of whom had kindly referred the case to me. An incision of four inches was made in the median line between the navel and the pubes. The pearl-gray sac was easily recognized, and the hand introduced to break up adhesions, which in spite of the fact that she had never been tapped, were quite numerous. The intestines, however, were not adherent. The sac was punctured with a bistoury and delivered as its contents flowed, strong and vascular adhesions being tied off with catgut and divided. The pedicle was secured by two locked stout silk ligatures, the sac cut away, and the stump dropped back into the peritoneal cavity. The incision was closed with silkworm gut and sterilized dressings were applied. The uterus was not sutured to the abdominal wall (on account of the excessively relaxed condition), but was easily replaced and retained in position by packing the vagina with sterile gauze. With the exception of a slight attack of pleurisy on the tenth day after the operation, her recovery was uneventful. The wound healed by first intention, and after four weeks the patient was discharged from the hospital.

The cyst weighed seventy-three pounds, and, though unilocular at the time of operation, bore traces of having been previously multilocular.

A SUPERNUMERARY NIPPLE.

By WILLIAM L. KANTOR, M.D.,

NEW YORK CITY.

Mrs. H—— and her husband came on the 10th of July last to engage me for her expected (first) confinement. Toward the close of the examination I noticed in the middle of the upper third of the right breast a macule with a slight depression in the centre. The woman stated that that was a wart and that it had been there ever since she could remember. There was, however, something peculiar about that wart, and on the 18th of August, at the time of the confinement, I again looked at it. I was still more convinced that it was not a wart, and yet the real nature of it was not apparent. I questioned my patient's mother, who was present, and she called it a birthmark. She said her daughter was born with it.

However, my repeated questioning about that "wart" had the effect of directing Mrs. H——'s and her mother's attention more closely to it. They looked at it, they handled it, and a few days later, after lactation was established, I was informed that some "matter" had been expressed from it. Were they sure it was "matter"? "Yes." "Perhaps it was milk." "Well——" The suggestion rather amused the women. They laughed heartily. But soon the tables were turned, for on manipulating the breast I could make drops of genuine milk come out from that part.

The following day I examined the spot with a biconvex glass. Although there was no sharp projection from the general surface, the areola was well defined, of normal pigmentation, and with a crater-like depression in the centre, where a drop of milk appeared

on slight manipulation of the area. Since then milk can always be made to come through this nipple. It comes also of its own account each time the baby is put to the breast. With the exception of this rudimentary supernumerary nipple, the breast appears normal. Palpation also elicits nothing unusual.

Mrs. H—— is twenty years of age, well developed, and a native of this country.

419 West Fifty-First Street.

Society Reports.

EIGHTH ANNUAL MEETING OF THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.

Held in Buffalo, September 13, 14, and 15, 1898.

Charles Rea Dickson, M.D., of Toronto, President.

First Day—Tuesday, September 13th.

The meeting was held in the rooms of the Society of Natural Science, Buffalo Public Library. The session was opened with prayer by the Rev. Orrin P. Gifford, and the mayor of Buffalo, Dr. Conrad Diehl, welcomed the association, and extended to its members the freedom of the city. After dwelling upon the rapid strides that had been made in electro-therapy since he was a medical student, and expressing his conviction that there was a bright future for the association and other workers in this field, he reminded his hearers of the advanced position that had been taken by the city of Buffalo in connection with notable features in electrical engineering, and suggested that arrangements be made by which those present might be permitted to inspect the large power house of the Buffalo Railway Company, and especially the enormous storage battery there—the largest in the world.

On behalf of the association, Dr. Francis B. Bishop, of Washington, D. C., made a fitting response to the address of welcome.

After the reception of delegates and guests and the presentation of reports of standing committees, the regular scientific work was taken up.

Phlebitis: A Clinical Study.—Dr. Margaret A. Cleaves, of New York, read a paper on this subject, giving detailed clinical records as well as general deductions therefrom and from a study of the pathology of the condition. She said that, as it was necessary to avoid any measure which would produce abrupt muscular action, the fast interruption of the induction coil, with the resulting tetanoid contraction, was not to be thought of. With the persistent closure of the continuous or galvanic current there was no sudden muscular action, such as would dislodge a thrombus, but instead there were gentle rhythmical contractions. A current which produced long wave-like contractions best fulfilled the requirements of such cases, and such an effect was obtainable by the use of the sinusoidal current. The indifferent contacts in her cases were placed over the lumbar enlargement and lumbo-sacral plexus, the negative pole being the active one. The greatest care should be taken not to break contact during the treatment. Her plan had been to use at first a continuous current of about eight milliamperes, and afterward a sinusoidal current, each sitting lasting only a few minutes. The treatment should be instituted in the acute or the subacute stage. The dose must be small at first in the cases coming under treatment early; often it should be less than five milliamperes. In the cases reported by her the duration of the treatment was about three months, but the improvement was often decided after one week. As a rule, the improvement was much more rapid in the first part of the treatment.

The Diagnostic and Therapeutic Relation of Electricity to Disease of the Central Nervous System.—Dr. A. D. Rockwell, of New York, read this paper, the special object of which was to correct some misconceptions regarding the limitations of electrical treatment in this class of cases. He said that when farado-muscular contractility was lost, or was greatly diminished, it pointed to a probable degeneration of the muscular fibre, which was most likely the result of impaired nutrition between the anterior cornua and the peripheral nerve distribution. A question which was often asked regarding cases of hemiplegia was, "Will electricity hasten the absorption of the blood clot?" His answer was that clinical experience had demonstrated so conclusively the great therapeutic value of galvanization of the head that it was difficult to believe that the good results so obtained depended upon reflex effect alone. Theoretically, the absorptive power of the electric current over a distant blood clot must be extremely small, and his own clinical experience had served only to confirm this view. In old cases, however, in which there were atrophy and decreased muscular irritability from disuse, there could be no objection to its employment. If applied longitudinally instead of transversely, unpleasant circulatory disturbances would be avoided, and the electrical treatment did no harm, even if it did no good. Very little was known about spasm of the vessels as a cause of hemiplegia, but he had seen two or three such instances. In spastic hemiplegia electricity not only was useless, but might be harmful. It was in poliomyelitis that electricity found its chief sphere of usefulness. In interrogating the muscles of children it was very important to eliminate pain and discomfort as far as possible. In this connection it was well to remember that in conditions of disease the isolated faradic shock was less painful than were the rapid ones, although this was not the case in health. In infantile paralysis the cells of the anterior horns were destroyed, or were being destroyed, and hence it was often asserted that electricity could not be of any use. The abolition of all faradic irritability meant damage to the nerve endings, which might or might not result in degeneration of the muscular fibre; the latter was determined by the application of the galvanic current.

Dr. G. Betton Massey, of Philadelphia, said that unfortunately there seemed to be a widespread belief that old cases of hemiplegia were good enough for the electro-therapeutist. Formerly he had been misled into using electricity in these forlorn cases, yet after the most persistent and faithful use of it he was free to say that he had never seen any benefit from it in this class.

Dr. Robert Newman, of New York, said that the absorption of the blood clot could be accelerated by galvanic applications. However, to apply the faradic current to the brain, as he had known general practitioners to do, was not only useless but absolutely injurious.

Dr. Francis B. Bishop, of Washington, D. C., said he could not entirely agree with Dr. Rockwell that electro-therapy was of no avail in cerebral hemiplegia. If these cases came under treatment sufficiently early, a good deal could be accomplished. Of course one would not expect to restore the parts that had been destroyed, but much could be done in the way of preventing degeneration of the muscles by keeping them stimulated and in proper tone until the clot had been absorbed. The speaker incidentally referred to an interesting case of hemiplegia with aphasia, in which he thought almost as much good had been done by educating the person to use the left hand as by the use of electricity. The improvement

in this patient had kept pace in a remarkable and interesting way with the education of the left hand in writing.

Dr. Cleaves agreed with the last speaker that, while the results from the electrical treatment of these cases of hemiplegia could not be called brilliant, improvement was observed sufficiently often to be encouraging. Referring to the question raised by the author of the paper, as to whether the current really reached the brain, she thought this could be answered in the affirmative, for the electrical conductivity of the human body was dependent upon the salts contained in the tissues, especially in the blood-vessels, and the brain was richly supplied with blood.

Dr. Henry McClure, of England, said that, while it was admitted that some cells had degenerated, it should not be forgotten that electrical treatment might prevent other cells from degenerating. He agreed with Dr. Massey that there was not the slightest improvement from electro-therapy in old cases of hemiplegia. He had seen several cases of long-standing poliomyelitis improve decidedly, and he believed that in all cases the constant current was indicated.

Dr. Rockwell, in closing, said that he could, if desired, present an extensive and interesting array of clinical results in cases of infantile paralysis treated electrically.

New Uses of the Undulatory Current in Gynæcology.—Dr. Georges Apostoli, of Paris, France, sent a paper on this subject. After describing a new apparatus for producing wave increase and decrease in the galvanic current, giving a voltage of from fifteen to twenty-five and a frequency of eighteen hundred to twenty-five hundred a minute, he stated his deductions from an extensive clinical test of the action of this current. The undulating current, he said, was a powerful analgesic, but its action was fairly localized. Dysmenorrhœa had been uniformly improved by it, so that patients who formerly had been compelled to resort to morphine at each menstrual period had been enabled to do without morphine and pass a painless period. With feeble vaginal applications of this current, hemorrhages had been aggravated. Indeed, in cases of hemorrhage the results with the undulating current had been inferior to those obtained with the galvanic current. In cases of constipation the undulatory current had usually caused a decided amelioration, and the results had been better from intra-uterine than from vaginal applications.

Dr. Massey said that a number of years ago, in a paper read before the Philadelphia Obstetrical Society, he had called attention to the excellent results that might be secured in cases of dysmenorrhœa by intra-uterine electrical applications during the period. At such times the uterus was invariably found to be open, and any physician making such applications would soon become sceptical concerning the so-called mechanical theory of dysmenorrhœa.

Electricity in the Treatment of Uterine Fibromata.—Dr. Felice La Torre, of Rome, Italy, sent a paper with this title, which was read by the secretary. He stated that myofibromata, not being malignant, should not be interfered with until they gave rise to serious symptoms. Electricity did not cause a fibroma to disappear, but it certainly relieved the pain and other distressing symptoms, and controlled the hemorrhages. It was valuable in interstitial or submucous fibroids when operation was not advisable. In cases of intra-uterine polypi galvanization tended to the formation of a pedicle. Before resorting to a cutting-operation for the relief of a patient suffering from a uterine fibroma, the general practitioner should give galvanization a fair trial. It lessened the physical suffering by calming the pain, and it restored the strength of the individual.

Electricity Employed in Gynæcology.—Drs. Georges Gautier and Larat, of Paris, France, sent a communication on this subject, which dealt in a general way with its more important features.

The Treatment of Uterine Fibroids by Small Currents Administered Percutaneously.—Dr. Richard J. Nunn, of Savannah, read this paper. After a vigorous plea for greater conservatism in all gynæcological treatment, the author spoke of his method of employing small currents percutaneously, avoiding altogether their cauterizing power. Such treatment, he said, could be carried out with inexpensive apparatus, and the method was well within the reach of the mass of general practitioners. Block tin was the best substance for the electrode, but he had employed, with much satisfaction, sheet lead. The milliamperemeter was not necessary, although an interesting refinement. With a cheap pocket compass and a little ingenuity one could extemporize a useful instrument, for the chief information needed was the fact that a current was actually flowing, and in what direction. His own observations with this method of treatment had extended from 1880 to 1890, and his results had been quite satisfactory, in spite of the fact that the exigencies of a country practice had rendered it necessary for his office nurse to make a large number of the applications.

Dr. McClure said that this interesting and practical paper brought up the important question as to how electricity acted. It had been taught that it acted as a caustic, yet Dr. Nunn's results certainly could not be explained in that way. Some years ago the speaker had endeavored to answer the question by supposing that it produced an effect—"a strain"—like that produced when electricity passed through a dielectric. The electricity, as it were, became entangled in the dielectric tissue. In this way it was possible to understand that a compression might be produced in the uterus, and that this might, in turn, lead to fatty degeneration. His theory was that on cathode closure the molecules were put on the stretch.

Dr. Nunn said that the tumors were amenable to treatment of this kind almost in proportion to their density: the harder the tumor the less the effect.

Menorrhagia and its Treatment by Weak Currents and Intra-Uterine Positive Silver Electrodes.—Dr. Adelstan DeMartigny, of Montreal, sent a communication on this subject, in which he advocated treatment, for five or ten minutes once or twice a week, in the intermenstrual period. The patient, he said, quickly became less nervous and the appetite improved. As a rule, the second period was much better and the third was almost normal, but the treatment should be continued for two or three months longer, the electrical applications being used only once or twice a month. The fact that the same results were not obtained with a platinum electrode lent some strength to the belief that the good effect was due partly to the formation of the astringent oxychloride.

Second Day—Wednesday, September 14th.

The Method for Using Cataphoresis in Certain Forms of Conjunctival Inflammation.—Dr. Lucien Howe, of Buffalo, read this paper, and presented several patients to illustrate what he had to say regarding the effect of cocaine and of a solution of suprarenal extract in reducing intense congestion of the conjunctiva. He said that it had been known for some time that if a five-per-cent. solution of the extract of the suprarenal capsule was instilled into an eye in which the conjunctiva was engorged, this engorgement would be quickly relieved. This solution of the extract, as ordinarily made, decomposed very quickly. Dr. Hubbard had recently devised a plan of

mixing the extract with a preservative, and of compressing it into discs which would keep indefinitely. But even with the suprarenal extract it was often impossible to obtain the full contracting effect; therefore cataphoresis was of decided advantage in connection with the use of either the suprarenal extract or cocaine. In glaucoma, for example, if both suprarenal extract and cocaine were used a better effect was obtained, but the result was still better if cataphoresis was called to our aid. The negative pole was applied to the outside of the lid, and the positive pole to the conjunctiva by a suitable electrode. The current should be very weak, for one of even half a milliampere would cause pain. The electrode which Dr. Howe employed, and which was found to be superior to the ordinary eye-cup electrode, was shaped like a shallow spoon. This spoon contained blotting-paper or a thin layer of cotton, thoroughly wetted.

Dr. Cleaves said that she had utilized the cataphoric treatment with oxidizable electrodes in conjunctivitis and trachoma, using silver, copper, and zinc at the positive pole, and securing the transference of the nascent metal into the conjunctiva. In one inveterate case of trachoma, observed jointly by a well-known New York ophthalmologist and herself, a complete cure had been effected. In conjunctivitis the silver electrode always acted most charmingly, and even long-standing cases might be cured.

Dr. Rockwell said that for many years he had used a glass electrode filled with clay and applied to the eye. He had seen good results follow the use of considerable current strength. He had employed cataphoresis extensively in the removal of hair, and had found that by using cocaine cataphorically this ordinarily disagreeable treatment could be made painless. Recently, however, during the application of cocaine in this way, the patient suddenly became unconscious and nearly died.

Dr. Massey said that, as Dr. Howe used a brass electrode connected with the positive pole, there was necessarily a cataphoric action of the brass, in addition to that of the cocaine. He thought the use of pure mercury preferable to the use of a sublimate solution. A gold needle might easily be amalgamated with mercury and used for this purpose. Of course, a minute portion of gold would be introduced cataphorically, but the quantity was so small with such mild current that it might be neglected.

Dr. Howe, in closing the discussion, said that with a lid of a certain thickness we did not know as yet just what current was necessary to produce any cataphoric action that could be demonstrated. If we could obtain some ocular demonstration, such as the formation of the blue iodide of starch, we could more nearly approach exactitude. He had endeavored to pass iodine or starch into the globe of the eye and obtain the characteristic color, but without success. In connection with this subject of cataphoresis of the eye, Dr. Howe exhibited, in the person of a boy, a remarkable and unique case of streptococcus inflammation, which had existed for three years and had resisted all other known methods of treatment. Under cataphoric treatment with a strong sublimate solution, the case had, for the first time, made satisfactory progress.

Electricity in Deafness and Stricture of the Eustachian Tube.—Dr. Robert Newman, of New York, described this method of treatment as employed by him. The electrode he used was an ordinary Eustachian catheter, with one inch of the distal end replaced by a silver tip shaped like an olive. This metallic tip of the catheter was connected with the negative rheophore, and the instrument was then introduced into the Eustachian tube down to the stricture. A current of a strength of from one to three milliamperes was turned on, and the obstruction overcome by electrolysis. Cases treated by himself and others were cited to show that electrolysis could cure stricture of the Eustachian tube.

Dr. Lucien Howe objected strongly to this treatment: (1) Because of the great difficulty in diagnosis; (2) because it had been shown that the pathological changes were not in the tube; and (3) because he considered the instrument employed a dangerous one. He said that nothing was more difficult than exactly to diagnosticate stricture of the Eustachian tube, except in certain very ephemeral forms. Moreover it was known that the pathological changes were not in the tube but elsewhere. Other changes than stricture of the tube were present in the later stages; Politzer had recently shown that in some cases that had been treated for years as cases of closure of the Eustachian tube there had been an ankylosis of the stapes. Owing to the very close proximity of the carotid artery, the introduction of the catheter was dangerous. Indeed, he could not understand how so large an instrument as the one exhibited could be passed sufficiently deep to reach the stricture.

Dr. Rockwell said he could confirm what the last speaker had said about the difficulties of diagnosis in these cases. His own opinion, founded on practical experience, was not in favor of the electrolytic treatment of cicatricial contractions, wherever found; and, while he admitted that negative was not considered as valuable as positive evidence, it was in his power to give very positive illustrations concerning the positive failure of electrolytic treatment of stricture, drawn not only from his own experience but from that of other and well-known clinical observers. It had not yet been thoroughly established that currents of from three to ten milliamperes were capable of favorably affecting cicatricial contraction.

Dr. Cleaves said that these differences of opinion regarding the value of the continuous current in overcoming strictures were dependent upon the degree of inflammatory deposit in the cases treated by the different observers. She was confident that recent products of inflammatory action could be removed by the tiniest current, but she did not believe the current would act beneficially when the inflammatory products had become firmer and partook more of the nature of cicatricial tissue.

Dr. Newman closed the discussion. He reminded those present that he had compiled seventeen hundred and fifty-five cases of stricture that he had successfully treated by electrolysis, and a committee of this association had examined these records and confirmed them. Regarding the objections of Dr. Howe, he would say that the instrument should be used only by skilled hands, and if the one exhibited was dangerous then the ordinary Eustachian catheter was dangerous. The diagnosis in his cases had been made by an accomplished aurist. Electricity did not act by dilatation but by absorption, hence no force was used.

Electricity in Acne Vulgaris and Acne Rosaceæ.—Dr. Grover W. Wende, of Buffalo, read this paper. He said that many cases of acne were due to sluggishness of the integument itself. This condition was to be combated by electric stimulation and irritation with sponge electrodes, or by electrolysis with the ordinary electric needle. In the use of electrolysis the pustules should not be opened; a solution of continuity was to be avoided. The electrodes were covered with moistened absorbent cotton, and their position was frequently changed until the desired area was well reddened. The strength of the current was regulated by the ability of the patient to bear pain. Usually five to ten cells were required, and the application should last for fifteen or twenty minutes. When there were indurated papules, it was sometimes ad-

visable to puncture the lesion in the centre with an irido-platinum needle attached to the negative pole. A current strength of from one to four milliamperes was usually sufficient. In one inveterate case he had made these punctures on alternate days for three months, and had effected a complete cure. Acne was often dependent upon sympathetic and circulatory changes in the integument. In the treatment of acne rosaceæ he had adopted Hardaway's plan of treating the hypertrophied blood-vessels. This consisted in attaching a needle to the anode and connecting the cathode to a bowl of water. The patient was directed to place one or more fingers in the water. Not more than three or four vessels should be treated at one sitting, and the same locality should not be treated more often than once a fortnight. A current strength of three or four milliamperes was sufficient. If the applications were carefully made, there would be no cicatrices.

Dr. Massey advised the use of larger and more widely separated pads in the treatment of acne vulgaris of the face. The pad might be easily constructed of wet absorbent cotton, over which a plate of soft metal was to be laid. If the cotton was thoroughly saturated perfect coaptation would be secured. If large areas were simultaneously treated, it would probably be necessary to use a current of considerable strength. He suggested that cataphoresis might prove a valuable adjuvant to the treatment of acne by electricity.

Dr. Cleaves said that in the treatment of acne the indifferent electrode (which should always be the positive) should be placed at some point which interposed the least resistance—usually the nape of the neck. A labile application should be made with the negative pole. Many cases of acne vulgaris yielded to an application of a slowly interrupted induced current—about twenty or thirty interruptions a second. Dr. Cleaves said that she had succeeded in curing some very obstinate cases of acne by the use of the induced current and attention to the general health. In one exceedingly stubborn case success had been achieved by the use of metallic cataphoresis with copper.

Dr. Emil Heuel, of New York, said he could confirm what had been stated regarding the freedom from scars in the electrical treatment of nævus. In one severe case he had obtained a cure after twenty-five sittings of five minutes each, using a current of from three to five milliamperes.

Dr. Alfred T. Livingston, of Jamestown, N. Y., said that his own experience was that electrolysis need not be followed by cicatrices when employed on the surface, as in the removal of hairs or of nævi. This was probably to be explained by the increased circulation and consequent improvement of the nutrition of the part. He found that moist clay allowed the use of a much stronger current than did moist absorbent cotton.

Dr. Wende, in closing the discussion, said that the prime requisite was to secure stimulation, and it did not seem to him that this was well attained by the method described by Dr. Massey. He believed that in acne there was a loss of tone and of contractile power of the sebaceous duct. As to the formation of scars, he said that as long as the operator kept out of the subcutaneous tissue there would be no scarring; on the other hand, if the subcutaneous tissue was destroyed, scarring could not be prevented.

Lightning Stroke and Eye Disease.—Dr. Ryerson, of Toronto, deputy surgeon-general, made some remarks on this subject. He said that these cases were quite rare, yet he had seen two instances in which eye trouble had followed lightning stroke. Seven or eight years ago, while a farmer and his wife and child were in bed, they were struck by lightning. The child was killed instantly; the father died in a few days, and after a time the woman, who was only twenty-five years old, became nearly blind. When he first saw her he found a soft cataract. In the course of a few weeks this matured, and after a month or two he made a satisfactory extraction in each eye, thus restoring vision. He had seen her very recently, and she could still see very well. The second case was that of a woman who, during a severe thunder storm, went to the door just as there was a blinding flash of lightning. When she was seen by him shortly afterward at the Toronto General Hospital, there were wide dilatation of the pupil of each eye and a very intense congestion of the conjunctiva and lids. She could not even perceive light. Under treatment, consisting chiefly of strychnine internally and eserine locally, she gradually improved.

High-Tension Current in Neuritis.—Dr. Francis B. Bishop, of Washington, D. C., read a paper with this title. He said that he was not opposed to the very careful use of the galvanic current in neuritis, but it seemed to him that better results were obtained by the high-tension current. The galvanic current followed the lines of least resistance, but this was not always the case with the high-tension current, and the higher the tension the more difficult it was to insulate the conductors. He had never used the static spark in these nervous patients. The voltage of the static current was known to be very great. Thus, Professor Trowbridge had asserted that an *x*-ray tube could not be properly excited by a voltage of less than 100,000. Dr. Bishop said that he had treated a number of cases of localized neuritis with the static current with perfect success, and even those treated with the current from a high-tension coil had been distinctly improved.

Dr. Massey said that in a number of subacute cases he had gotten very poor results from the galvanic current. On the contrary, the spark treatment in the chronic cases had been invariably successful in his experience, and he was convinced that high-tension applications were indicated in all forms of neuritis.

Dr. Cleaves agreed with the reader of the paper regarding the value of the high-tension current. Personally, she had used the convective discharge of a brush electrode, the applications being made for the general nutritional effect and also along the nerve. She recalled a case of ascending neuritis in which the suffering was so great that the patient had passed many sleepless nights. Immediately following the use of the high-tension current, the first good sleep was secured. The speaker said that she never used the galvanic current in these cases.

Dr. Bishop, in closing, said that he took the current from a shunt on one side of the machine. He did not claim anything special for the method described in the paper, except that it was agreeable and efficient and that the vibration was very rapid. As to the comparative merit of his method and the current obtained by the convective discharge, he would only say that in one case, after failing to observe any benefit from the use of the convective discharge, he changed to the method just advocated by him, and was pleased to note immediate and marked improvement.

Electricity in the Treatment of Goitre.—Dr. Charles R. Dickson, of Toronto, presented in this brief paper a synopsis of his views regarding the treatment of goitre electrically. In exophthalmic goitre he favored percutaneous applications with mild currents daily, the patient being in the recumbent position as far as possible. In engorged conditions of the thyroid he preferred to place the positive pole on the abdomen or shoulder, and make a percutaneous application over the thyroid for five or ten minutes. In slighter forms of hypertrophy he used an electrode the size of the goitre, with current strengths up to the

limit of tolerance. In the larger thyroids he aimed at destruction of the tissue with the negative pole, and the formation of a cyst within the goitre. In cystic goitres he evacuated the contents, refilled the goitre with saline solution, and made this the negative electrode. At the conclusion of the *séance* the fluid was evacuated through a drainage tube, and compression was carefully made and maintained. His aim was the obliteration of the cyst. Diet, medication, and hygiene were all-important factors in the treatment. Electro-puncture of the thyroid was a procedure requiring the greatest care.

President's Address.—Dr. Dickson, in delivering his address, aimed to make it clear to the general public that electro-therapeutics was a live subject, that it was not properly taught in medical schools, and that therefore the American Electro-Therapeutic Association had an important mission.

Ten-Minute Talks upon Electro-Therapy.—This feature of the programme was introduced by the statement of the president, that the object was to present in a condensed and practical form, free from technicalities, the salient points of electro-therapy which were likely to prove interesting and instructive to the general practitioner. A special effort had been made by the committee of arrangements to secure the attendance at this time of members of the medical profession living in Buffalo.

Functional Diseases of the Nervous System Treated by Electricity.—Dr. A. D. Rockwell presented a paper with this title, in which he dwelt more particularly upon neurasthenia. He said that the first thing in the treatment of a neurasthenic was to gain the patient's confidence. When he relied upon such drugs as the bromides, particularly the bromide of zinc, he depended chiefly upon electricity. Neurasthenia being a disease of exhaustion and malnutrition, there was every reason why electricity should be useful. Neurasthenia in the majority of cases was functional, and was generally curable. Electricity in neurasthenia increased cellular activity and favored the elimination of toxins. Traumatism or shock was capable of producing loss of conductivity through the neurons.

The Galvanic Current in Gynæcology.—Dr. G. Betton Massey read this paper. He asserted that the intelligent application of electricity would render unnecessary four-fifths of the major and minor surgical operations now performed on ambulatory cases of diseases of women. Irregular menstruation and menorrhagia could be so easily relieved by electrical treatment that he regarded with horror the prevalent treatment by dilatation of the cervix. The Apostoli technique was capable of curing at least eighty-five per cent. of cases of uterine fibroids, while the remaining fifteen per cent. were made neither worse nor better by the treatment.

Dr. F. B. Bishop said that when the condition was purely one of ovarian congestion and inflammation, without pus formation, his results from electrical treatment had always been excellent. He favored treating imperfectly developed pelvic organs by the current from a coil of eight thousand feet of wire, using the tension of the entire coil.

Dr. Massey said that while he agreed with Dr. Bishop about the superiority of the faradic current over the galvanic current in many cases, he had often used the galvanic current because of the associated ovarian neuralgia and menorrhagia. His practice was to apply the current by the usual vagino-abdominal method. One should not lose sight of the possibility of saving very many women who were now remorselessly subjected to mutilating operations. The pelvic organs were removed, and their removal was justified because there was a little inflammation present; whereas no such radical measures would be tolerated in entirely similar pathological conditions in other parts of the body. It sometimes required prolonged electrical treatment—possibly six months or more—yet he had never failed to cure such cases, and they were entirely within the domain of the general practitioner. He advised the use of a large cotton-covered electrode connected with the positive pole, and a current of fifty milliamperes for five minutes at a time. In ordinary cases of metritis from twenty-five to sixty or more applications were required.

Electricity in Genito-Urinary Diseases.—Dr. Robert Newman presented a brief paper giving a general view of this subject. He stated that most of the urethral strictures coming under his observation had involved the submucous tissues, yet, strange to say, Dr. Gouley absolutely denied the existence of anything to be absorbed. In the treatment of hypertrophy of the prostate by the galvano-cautery the applications could be made either through the urethra or through the rectum.

Orthopædic Uses of Electricity.—Dr. Louis A. Weigel, of Rochester, read a paper with this title. He said that there was no distinct branch of electro-therapeutics which was applicable to orthopædic surgery. In cases of infantile paralysis the function of the orthopædic surgeon was supposed to be to devote all his energies to the correction of existing deformities or to preventing the occurrence of such deformities. The neurologist often made the mistake of treating his cases by electricity, irrespective of the mechanical conditions present. As a consequence of disturbed equilibrium deformities were almost sure to follow, and hence, while electricity was a useful adjuvant, if only one method of treatment could be employed, the more important one was the mechanical treatment. In most cases of spastic paralysis operations were necessary. In most cases of lateral curvature electrical stimulation of the muscles was a useful aid. In the painful affection of the foot known as metatarsalgia, Morton claimed that there was a pinching of the nerve by the dragging down of the arch. None of the radiographs that Dr. Weigel had made, however, showed any such pinching. Flatfoot was another condition in which electricity was useful. Dr. Weigel then exhibited a large number of radiographs that he had made, and which illustrated the value to the orthopædic surgeon of this new surgical resource. Incidentally, he said, it was worth noting that he had used the static machine for *x*-ray work for over a year and a half, and had never produced the slightest *x*-ray burn. The exposures had varied in length from forty-five minutes to one hour. In no instance was the tube nearer to the subject than eighteen inches, and this he considered to be the secret of his complete immunity from such accidents.

Treatment of Malignant Growths by Means of Electricity.—Dr. G. Betton Massey gave a brief account of his method of treating malignant growths by mercurial cataphoresis. He said that the cataphoric transmission of nascent oxychloride of mercury and zinc from the electrodes introduced into the tumor furnished the means of carrying the destructive agent to any desired distance. Of course, the electrode was dissolved in the process. The patient was placed under ether. Very heavy currents were used. Thus, in a case in which half of the breast was involved, Dr. Massey would use one thousand milliamperes transmitted for about one hour, with occasional remissions so as not to interfere too much with the action of the diaphragm and of the heart. A large slough separated, as a result of the treatment, but it remained aseptic even for weeks at a time, because of the large quantity of mercury that had been introduced into the tissues. In order to have a pure mercurial cataphoresis, he now

employed a gold electrode. He was not content with simply amalgamating it, but had a contrivance by which a teaspoonful or more of mercury could be injected. He endeavored at one time to recover, by electrolysis, the mercury from the urine, but failed to do so. However, the mercury evidently got into the system, for several of his patients complained of tender gums, and unquestionably a number of them had been salivated. If the mercurial cataphoresis was tried upon a piece of meat, it would be found that the mercury was carried in only to a distance of three or four inches.

Surgical Uses of Electricity.—Dr. Charles R. Dickson, in a brief communication with this title, narrated in an elementary way what the general practitioner might expect to accomplish in this field with electricity. Thus, it might be used to promote absorption, to block up capillaries with bubbles of hydrogen, and to remove hair and small nævi from the face without causing visible scars. As to the mode of absorption, he stated his belief that fibrous tissue was never absorbed as fibrous tissue, but must first undergo fatty degeneration. Electricity might, however, give the appearance of having caused direct absorption by giving rise to atrophy of the fibrous tissue.

Third Day—Thursday, September 15th.

The Alternating Dynamo Current.—Dr. F. B. Bishop presented a paper in which he described a simple step-down transformer for use in this connection. He said that he had treated several cases of writer's cramp with this current. The patients had been previously treated with the galvanic current, and of their own accord had spoken of how much easier they felt after the alternating current. By means of the transformer the voltage was reduced from 104 to 4. The patient placed both hands in jars containing warm water in which salt or soda had been dissolved.

The Electric Arc Bath: A Clinical Report.—Dr. Margaret A. Cleaves presented in this report detailed clinical accounts of cases treated by the electric arc bath. Among these were cases of eczema, psoriasis, bronchial asthma, and pulmonary phthisis. Her observations in connection with the last-named disease were especially interesting. As she very pertinently remarked, it had long been known that sunlight was inimical to the growth of tubercle bacilli, and the value of sun baths had been demonstrated again and again. The electric-light bath closely approximated the sun bath, and, in addition, there was the production of ozone. A greater quantity of ozone was generated from the alternating current. She preferred the arc light because of this production of ozone, and also because of the fact that the rays from this light embraced a large part of the violet end of the spectrum. There could be no doubt, she said, that in man, as in plants, protoplasmic activity was increased by exposure to electric light. Her cabinet, she said, was six feet long, two and one-half feet wide, and seven feet high, and was lined with zinc, painted white. At each end were glass compartments containing the electric arc lights. The patient reclined on a wire-mattress cot. Each lamp had a reflector which allowed focussing the light on special parts. The patient was preferably nude, and the eyes were protected by dark glasses. The maximum of nutritional activity was usually observed at the end of the second week, and this would be expected from theoretical considerations as to the action of ozone.

Dr. Nunn said that the paper was interesting as emphasizing the old-time truth regarding the sanitary value of sunshine. Of course, where sunshine could be readily obtained, it must be admitted to be superior to artificial light. As modern chemistry had shown the atmosphere to be such a complex substance, it did not seem to him wise to say very much regarding ozone.

Mr. John J. Carty, electrical engineer, suggested that some of the effect might be due to radiation and some to emanations from the arc. In the latter connection it should be borne in mind that the carbon rods were commonly of complex composition, and not pure carbon, and, furthermore, that they were coated with copper.

Dr. F. B. Bishop said that he had had an opportunity of seeing the working of Dr. Cleaves' cabinet, and had been impressed with the rapidity with which the ozone had been generated and its quantity. As he had himself secured some excellent results in the treatment of the early stages of pulmonary phthisis by means of the ozone bath, he was inclined to attribute Dr. Cleaves' success chiefly to the ozone generated in connection with the arc light.

Dr. Massey spoke of the striking effect of sunlight on the vegetable world, and the mistake of modern civilization in so generally excluding the sun from dwellings.

Dr. Cleaves, in closing the discussion, said that she wished it to be understood that she did not know what it was that gave her these good results, though the clinical fact remained. In only the one case reported had there been a complete disappearance of the tubercle bacilli, but in all of the cases so treated there had been gratifying improvement.

Some Suggestions on the Possibilities of Cataphoresis.—Mr. John J. Carty, E.E., of New York, presented this paper, which was founded on some experiments that he had made regarding the use of cataphoresis in the attempt to secure painless dentistry. It did not seem to him that there was any part of the body which physicians should despair of reaching by cataphoric medication. A novel suggestion which he made was to use an O'Dwyer tube as the positive pole, and apply the negative pole to the neck in the form of a collar in cases of diphtheritic laryngitis.

Dr. Massey said that cocaine cataphoresis never failed in dentistry if properly conducted. The principal causes of failure were: (1) improper apparatus; (2) imperfect technique, such as not properly drying the tooth cavity; and (3) lack of willingness on the part of dentists to give the necessary time to the use of this method. The suggestion about using the intubation tube seemed an excellent one, and if this tube was of zinc and was freshly amalgamated at the time, he thought it would prove still more efficient, as the oxychloride of mercury formed was one of the most powerful antiseptics known.

A High-Frequency Oscillation for Electro-Therapeutic Purposes.—Mr. Nikola Tesla, E.E., of New York, in a paper with this title described his now well-known experiments with high-frequency currents, dwelling particularly on the construction of the apparatus and the possibilities of the future in the therapeutic application of this form of electricity.

Officers.—The following officers of the association were elected: *President*, Dr. Francis B. Bishop, of Washington, D. C.; *Vice-Presidents*, Drs. Ernest Wende, of Buffalo, and W. H. White, of Boston; *Secretary*, Dr. John Gerin, of Auburn; *Treasurer*, Dr. R. J. Nunn, of Savannah, Ga.

The next meeting will be held in Washington, D. C., on September 19, 20, and 21, 1899.

Lupus.—

R Salicylic acid	10 gm.
Creosote	20 "
Simple cerate	15 "
White wax	5 "

—Dr. P. J. Unna.

Therapeutic Hints.

Treatment of Gastrorrhagia with Warm Water.—Dr. Tripier (*Le Scalpel*, July, 1898) has used this treatment with marked success. When hæmatemesis or melæna appears in the stools, whatever may be the supposed origin of the vascular lesion, washing with warm water, 48° to 50° C., should be done two or three times daily and repeated more frequently if the blood has a tendency to reappear. The patient should be placed in a horizontal position during the lavage and should make no effort at retention.

Pruritus Ani.—First wash with water of camomile, added to a little saponified coal tar. Then apply oxide of zinc and vaseline, and powder freely with the following mixture:

℞ Camphor..... 2 gm.
Oxide of zinc..... 30 "
Bismuth..... 30 "
Talc..... 40 "

When the irritation has become less, paint every two days with a solution of nitrate of silver, four per cent. One may add to this at night a suppository of cocaine and extract of belladonna.—Brocq.

Pruritus Scroti.—

℞ Bichloride of mercury..... 0.3 or 0.5 gm.
Alcohol..... 25 gm.
Chloroform..... 5 gtt.
Water of camomile..... 25 gm.
Water of wild cherry..... 50 gm.
M. S. Apply.

—Leistikow.

Acute Pneumonia.—Dr. Raven in a paper read before the East Kent District Society concludes that, given a good atmosphere, a good bed, good diet, and good attendance, in the large majority of cases of acute pneumonia patients get well of themselves; and that an exaggerated importance is attached to various methods of so-called curative treatment, whether by ice or heat, brandy or blood letting, antimony or digitalin, or any other opposed plans of treatment.—*British Medical Journal*, June 4th.

Infantile Colitis.—Benefit is derived from hot compresses and from enemata of boiled water injected fairly high up into the intestine, care being taken not to introduce too much fluid at a time. Castor oil is the best kind of laxative for constipation. The diet should consist of light soups, well-stewed fruits, boiled fish, boiled eggs, and milk combined with magnesia. Warm douching, accompanied by friction, seems particularly good in some cases, but the abdomen should not be douched.—*Thèse de Paris.*

Tæniafuge.—

℞ Amorphous salicylic acid..... gr. vi.
Ethereal oil of malefern..... ♏ ix.
Essence of cinnamon..... gtt. x.
Gum arabic..... ʒ ij.
Distilled water..... ʒ iij.
Simple syrup..... ʒ iss.
M. S. To be taken fasting in the morning in two divided doses at an interval of an hour.

—Van Aubel, *Gazz. degli Ospedali e delle Cliniche*, May 19th.

Uncontrollable Vomiting in Pregnancy.—Dr. Geoffroy (*Le Scalpel*, January 1, 1898) indicates a new method of treatment based on the employment of very gentle massage. This author, who has for a long time employed prolonged palpation in the treatment of affections of the digestive tract, has observed in several cases of uncontrollable vomiting that there existed at a point in the digestive tract a localized spasm transferred by reflex irritation from the uterus. This spasm, according to Dr. Geoffroy, was localized at two points: first, at the junction of the stomach with the duodenum; second, at the point well down in the left iliac fossa, at the posterior part of this fossa at a point which is never any other than the ileo-pelvic angle of the colon, formed by the union of the fixed iliac part of the colon with the movable pelvic part. This spasm causes a permanent state of contraction, which deep palpation readily discloses. This peculiarity is for the writer so characteristic that when he encounters it in a woman who vomits or who has a cessation of the menses he diagnoses pregnancy. This contraction is encountered in subjects affected with various gastro-intestinal troubles, neurasthenia, the beginning of appendicitis, etc. It is a pathognomonic sign of reflex hyperæsthesia of the intestinal canal, of which the morbid symptoms vary from those produced by mild cardiac disturbances and simple nausea to uncontrollable vomiting. By using precautions to avoid pain in making gentle pressure, both slow and progressive with the ball and not with the extremity of the fingers, one can perceive at the point mentioned a series of nodules, ordinarily very small, which are hard and resisting, but which become softened in proportion as the digital pressure is gentle, slow, and progressive. There is a sensation of gas and of liquids under the fingers, with a slight gurgling, generally perceptible to both the physician and the patient. The induration ceases, the nodules disappear, and the discomfort that they have excited is replaced by a sensation of well being and an inclination to rest, which indicate that the time has come to suspend the treatment. In the first case in which the author applied this treatment, five or six séances were requisite to effect a complete cure. In general, two or three séances, sometimes only one, cause the vomiting to cease. It is useless to prolong the treatment in order to avoid a return of the trouble. The method is useful in all cases if properly applied, and is perfectly harmless.

"Death to Corns."—

℞ Ext. of cannabis indica..... 1
Salicylic acid..... 10
Oil of turpentine..... 5
Glacial acetic acid..... 2
Cocaine (alkaloidal)..... 2
Collodion..... q.s. ad 100

OUR LONDON LETTER.

(From our Special Correspondent.)

EAST LONDON WATER FAMINE—OFFICIAL REPORT ON MAIDSTONE EPIDEMIC—ROYAL INDIAN ARMY MEDICAL CORPS—BEHRING'S PATENT—QUACKS PROSECUTED—RECENT DEATHS.

London, September 2, 1898.

East London has again been plunged into the miseries of a water famine. After all the promises of the company which supplies this poor and crowded district and the assurances of its officials and engineers that the new works would suffice to meet all contingencies, a few weeks of warm summer weather are followed by a short supply. This is the third breakdown of the East London Water Company, and those who are unfortunate enough to reside in its district assert that on very short notice the constant supply was cut down to six hours, and those hours were not even specified. To the poor in crowded dwellings this is a terrible hardship, as they have no vessels in which to store water, and if they had their tenements are not fit places in which to expose the drinking-water. A letter in *The Times*, signed by twelve medical men, says that diarrhœa at once greatly increased, and expresses the opinion that the stoppage of the supply will as directly cause the deaths of hundreds as if they were actually poisoned. Of course a medical journal is chiefly interested in the sanitary aspect of such a calamity, and it is impossible at present to gauge the extent or the gravity of a water famine in an enormously overcrowded district, such as is the part of the metropolis at the mercy of the East London Company.

The defence of the company is that the prolonged drought is to blame. Think of it—few weeks of fine weather! As if England never had any summer! That such a failure of the company should occur for the third year is a sufficient answer to the absurd excuse.

Moreover, water could have been procured at first from the other companies, but the directors did not choose to buy it. They are now obliged by the public outcry to incur some expense, and have agreed to pay the vestries which have come to the rescue with water carts for the cost of that help. The difficulty of storage has been reduced by *The Evening News*, which opened a fund for the supply of one thousand three-gallon jars, heading the list with £100. Indignation meetings have been held, tales of misery told, and resolutions passed calling upon the authorities to relieve the grievance and danger to health of the million and a quarter of London's inhabitants who are affected. It is too clear that Parliament made a great mistake in accepting the estimates and assurances of the company after the last breakdown; and yet this company goes on collecting its dues as if its contract had been fulfilled.

Surely after this third failure of the company to carry out its duty the monopoly should be forfeited. Meantime there is a talk of uniting to resist payment of the water rate, on the ground that water was not supplied, and to take a test case through the courts. A summons has already been obtained by one house owner. The chief water examiner and the medical inspector of the government board have visited the district and recommend a free distribution of disinfectants, and the president of the board, Mr. Chaplin, has returned to town to confer with them and others. The sanitary inspectors under the health officers of the districts involved have also made an inspection of the poorer neighborhoods and found an alarming neglect of the drains.

The Whitechapel board proposes a conference of the local authorities, about twelve in number, with a

view to concerted action in an appeal for the infliction of penalties under the railways and canals commissioners act.

Some papers have remarked that the death rate has not risen, but they forget that it is too early for the returns to show the effect on the mortality.

The report of the inspectors appointed by the local government board to inquire into the late epidemic at Maidstone has been issued. It precisely corroborates the statements I sent you at the time. It is true that defects in the general sanitary condition were found, but the water was unquestionably the cause of the epidemic. The Fairleigh Spring was the one contaminated, as was suspected at the earliest stage of the outbreak. This spring offered all the conditions required; it was proved that the surrounding ground was often in a filthy state, and it was unprotected from such contamination. The medical officer, Dr. Adams, had often called the attention of the authorities to the dangerous sanitary state of the town. His recommendations were, unfortunately for the inhabitants, not adopted.

As was anticipated, the warrant establishing the royal army medical corps has been followed by another, issued on Saturday, extending the same organization to the Indian medical services. The two services are therefore constituted on parallel lines.

Much indignation is felt here against Professor Behring for seeking to patent his diphtheria antitoxin. As soon as it was reported that he had obtained a patent in the United States his action became the subject of a lively discussion, and hopes are freely expressed that his claim will be contested in your law courts. If he were to pay us a visit now, his reception would be very different from what it might have been some time since and would not be likely to gratify him.

Two or three quacks have been successfully prosecuted, and a coroner's jury has rebuked a practitioner for sending an unqualified assistant to visit a patient, requesting that the attention of the Medical Council should be called to the case.

One of the quacks had carried on his business for forty-six years, but the Defence Union interfered. He was convicted of using the term surgeon and fined, but the sapient magistrates found that in calling himself doctor he did not wilfully and falsely pretend to be registered. So on that count he got off.

Another person has been fined £5 for using the title of dentist, he not being registered.

The death of a nonagenarian doctor is announced in the person of Miles Astman Wood, M.R.C.S. He had attained the age of ninety-one. He died at Ledbury, where he began practice in 1830. Prior to this he had, after taking his diploma, studied for a time in Paris under Laennec and Dupuytren, and he naturally introduced the stethoscope into his neighborhood. He retired only some four or five years ago.

Among other recent deaths are those of the following: Dr. K. N. Bahadhurji, M.D., of the London University. He was but a young man when he was sent by his Indian colleagues to plead for Indian medical reform at the Carlisle meeting, 1896. He then issued a pamphlet on the medical and sanitary reforms needed in India, and made many converts to his views. He was physician to the first plague hospital in Bombay, and devoted himself to the sufferers during the epidemic.

Dr. Alexander Lindsay, aged eighty-two, on the 14th ult., formerly a favorite lecturer on medical jurisprudence in Anderson's University and examiner at the Glasgow Faculty. He retired about twelve years ago.

Deputy Insp.-Gen. E. W. Bawtree, M.D., died on the 13th ult., aged eighty.

Deputy Surg.-Gen. J. R. M. Lewis on the same date, aged seventy-five.

Deputy Insp.-Gen. J. Pringle, M.D., on the 23d.

Dr. T. F. I'Anson, J. P., of Whitehaven, died on the 19th ult., aged seventy-five. He was one of the oldest, if not the oldest practitioner in West Cumberland. His M.D. was of Aberdeen, 1848, the year in which he was appointed house surgeon to the Whitehaven and Cumberland Infirmary, where he succeeded in due course to the other appointments, at the time of his death being consulting surgeon.

OUR BERLIN LETTER.

(From our Special Correspondent.)

VACCINATION BENEFITS—DISPENSARIES AND PHYSICIANS—FEMALE POLICE PHYSICIANS—ROENTGEN RAYS IN BRAIN TUMORS—TR TUBERCULIN.

BERLIN, August 26, 1898.

SOME interesting statistics have recently been published bearing upon the history of small-pox in Germany. The opponents of vaccination claim that the disease never was entirely eradicated, but that, like a "creeping fire which is covered with ashes," it has lived on in spite of all measures taken to check it. According to exhaustive researches, it has been proved that the few isolated cases appearing in Germany have invariably been brought into the country from some foreign place not so well protected. From the following it can easily be seen how great the protection is. During the year 1896 only ten deaths from small-pox occurred in Germany, in other words, 0.19 per million inhabitants. While this exhibit is a gratifying indication of the benefits of State medicine in saving lives and lessening disease, the offset to the physician is not made in other desirable directions. In all matters connected with the welfare of the people he necessarily takes an unselfish part, and, from a purely business point of view, damages his own pecuniary interests. This he willingly does for the public good. In accordance with the law of compensation, however, he should be protected in other directions and be assured by the State a decent and competent livelihood. The contrary seems to be the fact when we reflect upon the abuses of medical charity which are making him poorer every year. The recently published annual report of the Berlin University clearly shows that during the past year the dispensary system has swollen into enormous proportions. The following figures give the number of patients treated in the various departments: Surgical, 17,643; medical, 11,254; eye, 12,443; gynæcological, 11,346; nose and throat, 3,411, etc. Besides this there were 2,857 confinements attended free by polyclinic physicians within the city limits. If we consider that almost every specialist has a private polyclinic, that the "sick-funds" take in a large part of the population, that quackery, especially in Berlin, has a large following, one can easily appreciate how hard the fight is for a physician who is literally struggling for his daily bread.

A new and keen competitor is also at present threatening the physician, in the shape of the fairer sex; although until lately no female could attain governmental recognition as a physician. All those practising medicine here have obtained the diploma elsewhere, principally in Switzerland. They have been employed in the police department in order to examine such women as are arrested on the street on the suspicion of prostitution. It once happened that an innocent girl was arrested and had to undergo the mortification of exposing herself to male physicians. In order to prevent in future such an occurrence, the above step was deemed advisable, that the modesty of such girls may be preserved. Only the first examination is to be

made by female physicians, and their services are dispensed with in the subsequent ones. By rights, according to the existing regulations, a female physician cannot be intrusted with this function, as only governmentally approved medical men are properly qualified. But this prohibition is easily evaded, as the secretary has the right to approve the appointment of any person who has distinguished herself by scientific work. Whether or not all the female physicians from foreign countries will distinguish themselves through significant scientific work must, naturally, be left to the judgment of the secretary. Although it is of little practical importance whether a male or a female physician carries on the police physician's duties, still it establishes a precedent which is not to be passed over so lightly.

In view of the present August heat the prominent medical societies have closed their doors until the end of September. At the last meeting before vacation of the Society of Charité Physicians, Professor Heubner demonstrated the Roentgen pictures of a brain tumor. The case treated was that of a child four years and four months old, of prodigious development. Besides the presence of choked disc, paraplegic symptoms and heightened patellar reflexes were found. How enormously rapid the child grew is shown by the following data: on July 4th the child's height was 108 cm., while on July 22d, two weeks later, it was 109.4 cm. The Roentgen picture showed an abnormal shadow starting in the region of the sphenoid bone and spreading out on both sides to near the parietal bones.

As a contribution to the TR tuberculin controversy, Dr. v. Zander reports the case of a patient who suffered from infiltration of the left upper lobe, catarrh of the right apex, and laryngeal ulcers, and in whose sputum many tubercle bacilli were found. He received altogether 59.5 mgm. of the substance; the temperature remained under 37° C., and he gained fifteen pounds in the course of the treatment. At present the scars of the laryngeal ulcers are hardly visible, and only here and there a bacillus can be found in the sputum.

In order to obtain good results with TR it seems to be necessary to be careful in the selection of the cases and also to follow Koch's directions implicitly. But we must always bear in mind that similar results are obtained with purely hygienic and dietetic measures.

MATERNAL IMPRESSIONS.

To the Editor of the Medical Record.

Sir: In the Medical Record of September 3, 1898, I was moved by the report of another "maternal impression" case, which serves to remind us that this same pestiferous hobgoblin is still extant. No greater fallacy ever infested the mind of man than this popular superstition concerning prenatal impressions.

The belief that if the pregnant female is frightened by a one-legged man the fœtus will suffer an amputation *in utero* of one of its legs, or that if the mother is scared by an innocent hare she will give birth to a hare-lipped offspring, is utterly without foundation; yet these stories are almost daily thrust upon us and usually regarded as judgments of Providence. While harelip and a few other of the common deformities are marks of hereditary degeneration or lack of development, the majority of them are mere accidents that happen to the fœtus as a result of traumatism or disease. I have seen grandmother, son, and grandson afflicted with harelip. Can any person argue that these were the result of fright? I have investigated a number of these cases and have invariably failed to find any substantial evidence that the results were traceable to maternal impressions. I am acquainted with a lady who, when five months pregnant, was assaulted by a tramp, which so frightened her that she screamed and sank to the ground and was unconscious three days. In due time she gave birth to a boy, a model of perfection in form. Observation teaches that there are at least ten infants with birthmarks whose mothers were not frightened at anything, where there is one with a history of fright. Recently I delivered a child with acrania whose head and face very much resembled a frog. There was no history of fright, but there was a history of a case of hydrocephalus and of two or three idiots among the near relatives.

The fœtus is practically a foreign body with no nervous connection with the mother; and it is impossible that the mother's mind could affect the offspring any more during gestation than during lactation. Human teratology teaches that all these congenital anomalies are traceable to natural causes, and any other explanation belongs to the "mystic and frightful domain of witchcraft and demonology." It is no easy task to untrammel the mind from this deeply rooted superstition; yet if one will zealously investigate these birthmark cases, his efforts will be amply rewarded by unearthing some of the most laughable incongruities.

James E. Pierce, M.D.
Middletown, Ind.

SOME PECULIAR MENTAL IDIOSYNCRASIES.

To the Editor of the Medical Record.

Sir: At times certain abnormal mental phenomena become manifest in individuals otherwise normal. These deviations, while not common to all people, are nevertheless not inconsistent with physical and mental stability. Let me cite a few examples. The peculiar nervous effect manifest in some individuals when touching velvet or the skin of a peach, producing a feeling of chilliness (cutis anserina), is wholly a reflex nervous phenomenon difficult of accurate interpretation. That this singular nervous effect is not dependent on any inherent property in the peach itself is proven by the fact that the same phenomenon or sensation of chilliness is not produced when the peach is peeled. While such an individual will handle and eat a peeled peach, he has a veritable aversion for an unpeeled one, and the mere thought of eating a peeled peach on which there may be still adherent a piece of the skin may produce the disagreeable sensation. These cited examples of mental eccentricity are of not so rare occurrence, and possess as much physiological as pathological interest, since the sensation of chilliness (cutis anserina) is produced independent of any existing disease. Now, to cite another singular example, I have seen in a boy and a girl, members of the same family, whose ancestors were free from serious nervous disease so far as could be determined, a singular impulse to touch the door a certain number of times before leaving the house; or if they happened to drop an object on the floor they would alternately pick it up and let it fall a certain number of times before feeling satisfied. They might touch the door of a room, say, six times before leaving it, walk a few steps and come back to touch it again. They might repeat these singular performances with other objects with which they come in contact during the day. This singular mental idiosyncrasy is difficult of explanation and neurological classification. Nordau might classify the subjects as degenerates, yet I would not do so. Although the singular eccentricities just cited were apparently inherited (occurring in two members of the same family), I will not deny that, like "habit chorea," they could have been acquired, first afflicting one, then the other. The children were otherwise well, and some years later, when the "habit" or eccentricity had entirely disappeared, both individuals (who

were at all times conscious of their absurd performances, laughed over them, and were surprised at their own actions. W. Moser, M.D.

Brooklyn, N. Y.

THE CONTROL OF MOUTH BREATHING.

To the Editor of the Medical Record.

Sir: In the Medical Record of September 10, 1898, Dr. Norburne B. Jenkins, of Knoxville, Tenn., publishes an article on "A Bridle for the Control of Mouth Breathing." Permit me to sound a note of warning against any such appliance.

Every human being, young or old, will and must breathe through the nose with the mouth closed, unless there be some pathological condition in the nose, retropharynx, or pharynx to prevent it. Physiologically this nose respiration is always present under normal conditions, and it is only necessary to refer to the text-books on physiology and laryngology for confirmation of this fact. Therefore the assertion of the author, that "such obstructions (viz., adenoids, stenoses, hypertrophied tonsils, and turbinated bodies, ecchondroses, nasal polypi, etc.) often appear as the results of the non-use of the nose in respiration," is based on a physiological impossibility.

On the other hand, if there are obstructions present, the author no doubt will agree with me that the best thing to do is to remove them. Then the patient will very quickly breathe through the nose without bridle or other mechanical appliance.

But unfortunately we are not always able to remove certain impediments in nasal respiration, say, for example, a chronic nasal catarrh. If in such a case we apply Dr. Jenkins' bridle to a child, two possibilities confront us: either the bridle is fastened so loosely, as I have frequently noticed with similar appliances, that the child still breathes through the mouth and not through the nose, in which case it is not harmful but of no use; or the bridle is fastened so tightly that the child cannot separate the jaws. In this case the child will choke to death. And it is this possibility against which I should like to warn my colleagues.

If a child cannot get any breath through the nose and if the mouth is tightly locked, provided there is no loss of teeth, giving space through which air could pass, there is only one chance left for such a patient —viz., suffocation. W. Freudenthal, M.D.

New York City.

TRAUMA AS A CAUSE OF APPENDICITIS.

To the Editor of the Medical Record.

Sir: In the last issue of the Medical Record I read with interest the article, "Trauma a Cause of Appendicitis.". While there undoubtedly are cases of traumatic appendicitis, I believe Dr. Small does not go far enough back. In many of our cases an attack appears to be stirred up by an injury, yet I think this happens nearly always in patients who have had a previous attack or attacks. I have had many cases in which the patients insisted that they had never had any trouble before, and in which I was convinced from the adhesions and general thickening I found that there had been previous attacks.

All operators tell us of adherent, thickened, and twisted appendices, and of adhesions binding the appendix and cæcum to adjacent structures; and we know how prone is such a mass to inflammation, how apt is such a case to develop an acute condition from trauma. But, to go farther back, I have rarely failed in my fresh cases to get a history of indigestion and diarrhœa some short time before the attack of local pain, and I believe most cases of appendicitis have their birth in the filling up of the appendix with liquid and septic fæcal matter, from which the fluid portion is afterward absorbed, leaving behind the irritating lump, which but continues the inflammation already present. Such a magazine may be kept sealed for a while, but how certain it is to explode in time, and what will more surely set it off than a trauma of some kind?

W. M. Brown, M.D.

Rochester, N. Y.

THE NEW ARMY TREATMENT OF TYPHOID FEVER.

To the Editor of the Medical Record.

Sir: As a sequel to the letter of Dr. W. Gilman Thompson in your issue of September 10th, under the heading, "The New Army Treatment of Typhoid Fever," I desire to report the case of a patient who was not stopped in New York City. G. S——, private, company A, thirty-fourth Michigan volunteers, entered my office September 1st, having been discharged from the detention hospital at Camp Wikoff three days previously. I found him with a temperature of 103° F., dry cracked tongue, sordes on the teeth, tympanitic abdomen, and suffering from a profuse "pea-soup" diarrhœa, much prostration, and an irritable stomach. I asked him if he had a fever when discharged. He replied that he did not know; that during the two days he was in the detention hospital he was at no time examined by a physician, and that when one appeared it was only to ask him if he wished a furlough. Thinking that if he was to recover he must escape from the lack of treatment he was receiving, the soldier replied in the affirmative, and with two other members of his company, in little better condition than himself, made his way as best he could to Michigan. I placed him in Mercy Hospital in this city, where he has since been very ill with a typical attack of typhoid fever.

Here is a patient who actually scattered the typhoid germs all along the railroad track from Montauk Point to Northern Michigan, and is still in considerable danger of losing his life from so doing.

W. T. Dodge, M.D.

Big Rapids, Mich.

FREEDOM FROM SMALL-POX OF THE ARMY.

To the Editor of the Medical Record.

Sir: Apropos of the editorial articles in your issue of September 10th, on "Army Surgeons" and the "End of Compulsory Vaccination in England," may it not be well to call attention to the fact that, notwithstanding there has been much suffering in the army of the United States since the beginning of the war with Spain, from typhoid and yellow fever, dysentery, etc., not one case of small-pox has occurred—not even of the modified type?

Hitherto, so far as I can ascertain, unless in the English army, there has been no war of any importance in which small-pox has not been one of the sources of distress and mortality.

Starling Loving, M.D.

Columbus, Ohio.

Compensation for Twins.—One has to read a French journal to learn to what length American enterprise can go. We learn from the *Lyon Médicale* that an insurance company has been started in this country to insure against the birth of twins. Provided a first payment is made by the enceinte woman at the beginning of pregnancy, before twins could be diagnosticated, the company will pay a large indemnity at the time of accouchement if there is more than one child. Whether or not the sum is in proportion to the number of children we are not informed.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 17, 1898:

	Cases.	Deaths.
Tuberculosis	169	145
Typhoid fever	209	44
Scarlet fever	49	7
Measles	33	2
Diphtheria	102	18
Chicken-pox	4	0
Cerebro-spinal meningitis	0	8
Laryngeal diphtheria (croup)	7	4

An Ideal Sanatorium.—S. Berkheim and Blanchet (Paris) say that although the isolation of consumptives in hospitals is a prophylactic process of much value, it is not very useful to the patients themselves, who, placed in indifferent sanitary conditions and in an impure atmosphere, derive relatively little benefit from the measure. What is needed are sanatoria constructed expressly for consumptives, at altitudes of eight hundred or fourteen hundred metres, far from the dwellings of men, and particularly from any large centre of population. The authors suggest the following plan of sanatorium as a type: An immense central building, connected with two wings by vast glass-covered galleries. On the south front there should be a gallery, two hundred metres in length, for the open-air treatment. All the bedrooms should have a southern aspect, and should resemble a surgical operating-room in appearance and in furniture; they should be capable of being easily made aseptic. Each one should have accommodation for only two patients. As regards the financial side of the question, the authors contend that if the sum recently voted by the Paris municipal council for the isolation of consumptives were to be devoted to the construction of sanatoria, the city of Paris would be able at once to have twelve model sanatoria, which would accommodate 12,960 consumptives every year. This would have the further advantage of setting free a large number of beds in the general hospitals, which are badly needed for other patients—*British Medical Journal*.

When may Women with Heart Disease Marry?—Dr. Kisch (*Therapeutische Monatshefte*, February, 1898) says the chief points to be considered are: (1) the kind of heart disease; (2) its duration; (3) the presence or absence of compensation; (4) the general health; (5) the social position of patients. (*a*) They may marry if the disease is not of long standing, compensation is good, and the general health is not undermined. They will have during pregnancy, and still more during and for a time after delivery, many troubles due to their heart, but in by far the greater number of cases there will be no danger to life. This applies to well-compensated mitral regurgitation and stenosis, aortic regurgitation, fairly marked sequelæ of pericarditis, and to muscular degeneration if not too far advanced. The patients must also be in a position to spare themselves bodily exertion as much as possible during pregnancy, to avoid mental excitement, and to have constant medical supervision. (*b*) The prognosis is not so good if the patients are very anæmic or nervous, or advanced in years, or if the valvular disease is congenital or acquired in childhood. In these cases the physician should advise against marriage, or at any rate point out that the disease will almost certainly become worse after marriage. (*c*) Marriage is to be absolutely forbidden as dangerous to life when compensation is failing or when there is advanced muscular degeneration. In all cases in which there are dyspnœa, palpitation, and quickened pulse on slight exertion, or marked œdema not disappearing after rest in bed; when there are a tendency to arrhythmia, scanty urine with albumin, and attacks of irregular small pulse, coldness of the extremities, nausea, dyspnœa, syncope, etc., marriage is dangerous, whether the cause of the symptoms be valvular disease, diseased arteries, or impaired cardiac muscle. Even those for whom marriage is allowable must follow certain rules strictly: (1) Coitus must not be frequent, and must be continued to the end of the orgasm; otherwise reflex heart troubles and depression result. (2) They must not have more than one or two children, as with every pregnancy the strength of a diseased heart diminishes in geometrical progression. If this rule is followed, induction of premature labor will be seldom necessary; and luckily so, since, when it is, the results are very unfavorable.

Baths of Nauheim.—Dr. Richard Douglass Powell (the London *Lancet*, April 9th), in an article entitled "The Principles which Govern Treatment in Diseases and Disorders of the Heart," says: "The strong brine and aerated baths of Nauheim and other places are unquestionably of much service in some circulatory disorders. They are perhaps most suitable for cases of chronic rheumatism and gout associated with high arterial tension and secondary cardiac disturbance. In cases of functional excitement of the heart's action in connection with quiescent or only imperfectly compensated valvular affections they may be used; in the latter cases at first in combination with more or less complete rest rather than with graduated exercises. In the high-tension and less quiescent cases the higher temperatures, calculated to lower tension and to stimulate surface circulation, are more useful. In the more neurotic cases with sound hearts the more tonic and comparatively lower temperatures may be employed in shortened duration. It is well pointed out by Dr. Groedel that the baths and exercises are two separate therapeutic agents and that in perhaps only twenty per cent. of the cases are they usefully employed in combination, although massage may be more frequently employed. Beneke, who originated the bath treatment at Nauheim, was very sound in his doctrine to avoid all gymnastic exercises until after the lapse of six months from any acute endocarditis."

Health Reports.—The following statistics concerning small-pox, cholera, yellow fever, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending September 17, 1898:

SMALL-POX—UNITED STATES.

		Cases.	Deaths.
Michigan, Otsego	September 10th	Reported present.	

SMALL-POX—FOREIGN.

		Cases.	Deaths.
Brazil, Rio de Janeiro	July 20th to 27th	2	
India, Bombay	August 2d to 9th	..	1
Calcutta	July 31st to August 6th	..	2
Norway, Christiania	August 20th to 27th	1	
Russia, Odessa	August 13th to 20th	2	
Odessa	August 20th to 27th	4	
Warsaw	August 13th to 26th	..	3

CHOLERA.

		Cases.	Deaths.
India, Calcutta	July 24th to July 30th	..	2

YELLOW FEVER—UNITED STATES.

		Cases.	Deaths.
Louisiana, Franklin	September 5th to 13th	42	2
Mississippi, Jackson	September 10th	2	
Orwood	July 30th to September 1st	41

SOME DESPERATE CASES OF TYPHOID FEVER TREATED WITH AND WITHOUT COLD BATHS.

BY SIMON BARUCH, M.D.,

NEW YORK.

THE trend of medical opinion may be readily ascertained by consulting the files of a wide-awake medical journal. The true position of the bath treatment of typhoid fever within the past decennium may be gathered from the following quotations from the MEDICAL RECORD. Referring to a paper on this subject, read before the State Medical Society, the MEDICAL RECORD of February 16, 1888, says editorially, that "if the author succeeds in arousing the profession to a realization of the fatality of typhoid fever in our midst, and in directing attention to the success of the cold-bath treatment, which, for obvious reasons, has not yet obtained firm footing, the outcome may be valuable.

"It will be difficult to persuade the profession, which has been long under the dominion of the *laissez-faire* policy, to adopt the heroic method of cold bathing. The most important point made by the author seems to us the emphasis placed upon the object of the cold bath being antifebrile rather than antithermic, inasmuch as its action is chiefly directed toward the neutralization of the febrile toxæmia due to the typhoid process."

That the continued agitation of the latter point has "aroused" the leading teachers and practitioners of this city and country to the "realization" referred to by the MEDICAL RECORD is evident from the following quotation from an editorial in the issue of May 7, 1898, nine years later:

"Advocates of the bath treatment seem to be increasing in number. It is generally conceded that excellent results are to be obtained by judicious cold-water treatment, and the closer the Brand method has been followed the better the reports seem to be."

That the MEDICAL RECORD voices the opinions of the leaders of medical thought may be gathered from discussions in our medical societies and from the records of our great hospitals.

In his first plea for the Brand bath the writer insisted upon the necessity of following the strict technique of Brand. While he still holds that when cases are seen in the first stages of the disease the latter is absolutely essential to success, a large experience has convinced him that in the later stages of cases which have not in the beginning been treated by the Brand bath a decided deviation from the latter is imperative. Some of the following histories will illustrate the proposition:

Mr. G——, aged thirty-two years, seen with Dr. Nicolai, in the fourth week of a severe typhoid. The patient had suffered during the past few days from decided cardiac failure, with its frequent accompaniment of renal inadequacy. An eminent consultant had suggested alcoholic stimulation and digitalis, but the patient's condition grew worse until his life was despaired of. I found him in a semicomatose condition, with eyes half closed, occasional twitchings of the facial muscles, subsultus tendinum, tympanites, and muttering delirium. Touching his body produced short but mild convulsive movements. The urine was scant; the quantity drawn during the past twelve hours had been ten ounces. Several bloody stools had been passed. The indications of treatment seemed to be to stimulate the failing cardiac innervation, and to remove uræmic poisoning by enhancing cutaneous and renal activity. The external use of cold water in any form was contraindicated by the condition of the cerebro-spinal centres. Hence hypodermics of strychnine, one-thirtieth of a grain every three hours unless contraindicated by trismus, were substituted for digitalis, and the nude patient was snugly wrapped in woollen blankets and given six ounces of cold water every two hours, alternated with six ounces of milk, until he perspired freely. During the next twenty-four hours forty ounces of urine were drawn. The first sound of the heart was stronger, despite the passage of another bloody stool. Improvement of cardiac and renal action continued and the patient made a slow recovery.

Mr. L——, aged twenty-six years, seen with Dr. Baran, had been ill with typhoid fever five weeks. The morning temperature had during the past week registered 99° F., but usually reached 102° F. or more in the evening. An eminent consultant had advised large doses of quinine and other judicious treatment, which, however, failed to control the fever. I found the patient greatly emaciated, too feeble to move in bed, but with clear intellect; pulse, 150; first sound feeble; no intestinal or other complication. The fever seemed to be due to sepsis, as was also the cardiac adynamia, both being the sequels of an exhausting typhoid which he had survived only under the most judicious management. Cold baths were out of the question. With little hope of benefit, ablutions of 65° F., carefully made, with friction over portions of the trunk only, every two hours, and guardedly repeated in accordance with reactive capacity, were advised. The patient being so feeble, the technique was carefully explained to the nurse. Intelligently and actively executed under Dr. Baran's supervision, this simple hydriatric measure, added to the judicious nutrition and stimulation already in operation, rescued this man from most desperate straits.

How much so simple a procedure may accomplish even in the earlier stages of the disease also, is illustrated by the following history:

M. W——, aged thirty-five years, seen with Dr. Simpson, had been ill five days, temperature ranging from 102° to 106° F., pulse from 120 to 140. Urine, examined by Dr. Simpson, contained albumin and granular casts; quantity during past twenty-five hours, twenty-seven ounces. The patient was delirious, muttering, sleepless. Up to this time the treatment had been homœopathic, with alcohol sponges for temperature reduction. This was withdrawn and for it were substituted ablutions at 65° F. every two hours, and hourly compresses at 60° F.; internally, five drops of diluted hydrochloric acid in water, followed by six ounces of cold water. Under these the temperature fell to 102° F. It fluctuated between 101° and 102.5° F. for five days, gradually falling every day or two until

it reached normal in four weeks, so that a tub which had been ordered proved unnecessary. The pulse never exceeded 100 after the second day of the simple hydriatic treatment, and averaged 80 during the last two weeks of the disease. The kidneys responded in a marked manner. The quantity of urine increased in one day to 60 ounces, registering afterward 87, 92, 98, 117, 113, 123, 90, 116, 82, 119, 82, 112, 81, 83, 90, 76, 86, 86, 90, 70, 80, 82, 79, 60 ounces by exact measurement. Albumin and casts disappeared in ten days. That these results were accomplished without cold baths is worthy of remark, and may encourage those who are timid in advising the latter in the more systematic hydrotherapy of typhoid fever.

The following case, from the records of the J. Hood Wright Hospital, is of interest as demonstrating how a modification of the Brand method and a substitution of affusions may lead to a successful issue in the most desperate condition:

E. J. C——, aged twenty-seven years, was sent to the hospital by Dr. Frank Daniels, after thirteen days' treatment in a boarding-house, where his temperature had ranged from 103° to 105° F., and his pulse from 120 to 150; he had most of the time muttering delirium. When admitted he was dull and apathetic, his tongue was dry and brown, the teeth were covered with sordes, the skin was cyanotic, abdomen tympanitic, subsultus marked. Three baths of 80°, 75°, and 70° F. for fifteen minutes during the night reduced the temperature one degree but did not remove the subsultus and mental apathy. The temperature being 102.2° F., affusions at 60° F. were substituted for the bath, to relieve stupor and improve the heart action, six ounces of milk, alternated each two hours with the same quantity of cold water, were also used. In two days the quantity of urine was forty-five ounces, containing albumin and hyaline and granular casts. The mental condition was decidedly improved by these cold affusions. Stimulants were discontinued and two ounces of strong coffee substituted before each bath, alternating with affusions, according to the condition of the patient; the former being used when the temperature reached 103° F., the latter when it was below. Compresses at 65° F. were continued hourly when the patient was awake. After seven days' treatment the mind became more clear and tympanites disappeared; the temperature was 101° F. Affusions were now given as a cardiac tonic. On the following day the temperature rose to 105° F., and the abdomen was again distended. Baths at 70° F. every three hours, with friction, given three times at four-hour intervals, reduced the temperature to 100° F., when affusions were resumed. During the next five days the temperature did not go above 102.8° F. A half-pack at 65° F. was given every hour; the temperature again rose to 103.4° F., but was reduced by one bath at 70° F. for ten minutes. The fæces now containing blood clots, baths were discontinued. After the temperature had been below 100° F. for several days, new rose spots appeared on the abdomen, and the temperature again rose to 103° F. Baths at 70° F. for ten minutes were now resumed every six hours until the temperature remained below 102.5° F. One month after the patient's admission the temperature registered normal. Six weeks later he was discharged.

Commenting upon the case before the Harvard Medical Society, Dr. Daniels, who had followed the case after its transfer to the hospital, said: "I have no doubt whatever that the man was saved by the application of the Brand baths and cold affusions over the head and shoulder, although begun in the third week."

Mrs. P——, aged forty years, was seen with Dr. E. J. Ware at midnight, when I found the family engaged in taking a sad leave of the patient, who was said to be dying. She had been ill six weeks and had been seen by several consultants. Pulmonary hypostasis, a feeble rapid pulse, anxious countenance, absence of first sound, were some of the manifestations encountered. The temperature had recently ranged between 100° and 103° F. The most judicious treatment had been assiduously applied, and during the past few hours hypodermics of brandy had been used. Here cardiac adynamia due to sepsis again confronted us, for which the following treatment was suggested: Hypodermics of strychnine, one-thirtieth of a grain every three or four hours; wet chest compresses at 60° F., cautiously applied every hour, the method being explained to the nurse; ablutions at 70° F. every two hours; regular alternate administration of milk and water, six ounces, every two hours. These measures stimulated the failing heart, removed hypostasis, and initiated a tedious convalescence.

Miss P——, aged thirty years, was seen at Long Branch with Dr. Harry Pemberton. She had been ill with typhoid fever four weeks and had been treated with cold tub baths. She was now sleepless, actively delirious, singing and muttering constantly, failing to recognize any one. Large hypodermics of hyoscine had somewhat controlled these threatening manifestations. The temperature had also yielded, and had been running below 100° F. for several days. Suddenly it had risen to 105° F.; a new crop of spots appeared, the abdomen became more tympanitic, diarrhœa again ensued, and the whole case assumed a most desperate aspect. The first indication being to produce sleep, a wet pack at 70° F. was applied by a skilful nurse, with gratifying result. This was repeated once in twenty-four hours, and full baths at 70° F. for ten minutes, every four hours when the temperature was 103° F. or over, were applied, followed by hourly trunk compresses at 60° F. The temperature and pulse improved under the treatment, until blood clots in the fæces demanded cessation of baths. The temperature rose again. Baths were resumed when blood disappeared, and they were continued for a week, when the temperature remained below 103° F. Compresses were continued until the temperature ceased to rise above 100° F. The wet pack continued to produce sleep, although the mind had not cleared before my departure from Long Branch. The patient made a slow recovery, as I was kindly informed by Dr. Pemberton. I had the singular experience of receiving a letter from this young lady, in which she expressed her gratitude to me, of whom she knew only through Dr. Pemberton's courteous mention, not remembering my presence during an attendance of ten days.

Remarks.—It may be noticed that in the recital of the above short histories, neither sponging nor the ice coil has any place. The writer has abandoned both. They are relics of the time when temperature was the point of attack in the treatment of typhoid fever, and cold water was applied for its reduction. Since the discovery of coal-tar products, it has become known that water cannot vie with these in antipyretic value, and that temperature reduction alone does not fulfil the therapeutic indication. Abundant clinical observation has also demonstrated that the lethal element in typhoid fever is a toxæmia which overwhelms the nervous system, according to its intensity, and depreciates all the vital organs which depend upon the integrity of the nerve centres for normal activity. To this toxæmia may be ascribed the high temperature, stupor, delirium, feeble heart action with its hypostatic conditions, renal stasis, etc., to which the patient so often succumbs. The application of cold to the cutaneous surface by ablutions, affusions, or baths produces a shock. This is followed, if judiciously graded, by a reaction, the stimulating effect of which is conveyed to the central nervous system, arousing it

from a lethargy which, in mild cases, is manifested by the rapid pulse, shallow respiration, elevated temperature, scant secretions, and in severe cases by cardiac failure, delirium, stupor, hypostasis, etc. Renewed energy is conveyed to the organs which maintain life and which have been crippled by reason of defective innervation. This is the prominent and important therapeutic principle, the recognition of which by the lamented Brand has saved many lives, and a correct understanding of which makes the physician independent of methods. The histories are cited to demonstrate the latter proposition; they show that while the full cold bath with friction is the ideal method, the ablution and affusion may with advantage be substituted for it in some cases, judiciously selected and applied. Sponging cools by evaporation. The small quantity of cold water used, and the slight friction produced by a soft sponge passed over the skin, create little or no shock and subsequent excitation of the cutaneous nerves, which in other procedures stimulate the depreciated nerve centres and counteract the lethal effect of the toxic agents circulating in the blood.

The ice-water coil cools only the part beneath it. It contracts the cutaneous arterioles, as is evident from the cyanosed appearance of the skin, and thus prevents all other effect. The continuity of its action prevents the shock and subsequent reaction required. While frequent sponging is far better than no water treatment at all, it may be advantageously discarded, when the cold bath is strenuously objected to or contraindicated, for ablutions, affusions, and trunk compresses, the technique of which may be gathered from works on hydrotherapy, and which should be closely followed.

51 West Seventieth Street.

THE DIFFERENTIAL DIAGNOSIS AND TREATMENT OF CUBAN AND CAMP FEVERS.[1]

By CHARLES E. NAMMACK, M.D.,

VISITING PHYSICIAN TO BELLEVUE HOSPITAL; CONSULTING PHYSICIAN, GOUVERNEUR HOSPITAL; PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK.

From July 20, 1898, to September 22, 1898, there were admitted to Bellevue Hospital three hundred and sixty men in the service of the United States army and navy. Of this number three had died before the last-mentioned date, and of those remaining in the hospital at the time none was likely to die. The surgical wards had treated one hundred and ten of these patients with one death, and the medical wards two hundred and fifty-one with two deaths. Of the medical cases, fifty-three were treated in the fourth medical division, under the supervision of the writer, without a death. Some of these men had been in the Cuban campaign; others had not been sent farther South than Florida; others had been in camps at Chickamauga and at Montauk Point. The prevailing form of illness among the soldiers from Cuba was malarial fever of the quotidian variety. In a few of these cases the crescent variety of parasite (Hæmatozoon falciparum of Welch) could be demonstrated, but the majority seemed to depend upon a double infection with the ordinary tertian parasite. No case was diagnosticated as malaria, or treated by quinine, until the specific protozoan parasite had been found in the blood. The routine plan of treatment was an initial dose of five grains of calomel with fifteen grains of bicarbonate of sodium, followed by the old-fashioned formula of the late Alonzo Clark, to wit: ten grains of sulphate of quinine with one grain of powdered opium and three grains of powdered capsicum, administered in soft capsules. Then smaller doses of the same combination were given every four hours, until the patient had been seventy-two hours without fever. Treatment of the coexisting anæmia was then commenced and continued until the patient's discharge from hospital. The results from this therapeutic procedure were in the highest degree satisfactory, very few cases resisting the action of the malarial remedies for more than seven days. One case of comatose pernicious malaria received one hypodermatic injection of twenty grains of bimuriate of urea and quinine, and afterward stiff doses of quinine by the mouth. He was a Rough Rider, with a sound heart and kidneys, and a determination not to die. He alternated between delirium and coma for five days, but left the hospital cured on the eleventh day. In every case in which the administration of quinine was not followed by a breaking up of the fever and an immediate improvement in the clinical symptoms, specimens of the blood were sent to the board of health laboratory for the Widal test. A positive reaction was obtained in two cases, in which our own examinations had previously demonstrated the presence of the malarial hæmatozoon. Waiving for the present the question of whether the Widal reaction is a reaction of immunity or a reaction of infection, a positive result in the blood test was taken to mean that the patients were suffering from a typhoid fever made irregular by admixture with malarial poison. For the purpose of getting a little more bacteriological light on this question of mixed infection, samples of the fæces and urine of such soldiers as showed a positive reaction to Widal's test, and also showed the presence of the malarial hæmatozoon in the blood, were sent to the board of health laboratory, but the bacillus of Eberth was not found in any case. Nevertheless the clinical histories, together with the blood examinations, enabled us clearly to place each case in one of three divisions, *i.e.*, malarial fever, typhoid fever, or typhoid fever complicated by malarial infection. In other words, we found no reason to recognize a distinct type of continued fever which is neither malarial nor typhoid, or one which is a compound of both—the so-called typho-malarial fever. As a rule, in these cases of mixed infections the activity of the malarial plasmodium was shown early in the course of the typhoid disease. In one very interesting case, however, that of a private in the thirty-third Michigan volunteer infantry, the malarial symptoms remained latent until he was ready to get out of bed from a severe typhoid, when characteristic chills with intermittent fever developed, and the tertian parasite was found in abundance in his blood. Previous examinations of his blood for the malarial parasite had invariably been negative. Of course the occurrence, late in typhoid fever, of chills with fluctuating temperature, would not alone have warranted us in dosing this patient with quinine, as this might have been caused by factors other than malarial, but microscopical examination of his blood clearly pointed out the therapeutic path. In every case of differential diagnosis between malarial and typhoid fever, the final decision was reached by examination of the blood, and in none was it necessary to employ the therapeutic test of quinine. When the malarial hæmatozoon could not be found, some help in diagnosis was afforded by the Ehrlich diazo reaction in the urine. According to Thayer, this reaction occurs only in six per cent. of cases of malaria, but is invariably present in typhoid fever. The results of the Widal test were not so convincing as they usually are in cases of typhoid fever of Northern origin. They were especially disappointing in the cases of undoubted typhoid fever developing at Chickamauga, in view of the fact that this reac-

[1] Paper read before the Medical Society of the County of New York, September 26, 1898.

tion is said to have been present in 97.9 per cent. of nearly five thousand cases reported by various authors.[1] Of one thousand and nineteen cases in Minnesota, the reaction was obtained in all but three before the twenty-second day.[2] This discrepancy may be due to the fact that there are clinical and anatomical differences between typhoid fever in the South and the North—the disease being much milder in the South.[3] Regarding the causes of typhoid fever at Chickamauga and Montauk, the writer is not qualified to speak from actual observation, and will not trust himself to speak from what has been told him by the soldiers. The charts told their own story of men being sent on long railway journeys in the full flush of typhoid fever, and arriving in New York exhausted, emaciated, and despondent. Their ready response to simple treatment in clean beds, with abundant liquid nourishment and adequate faithful nursing, forms the bright side of the picture. We have no specific treatment for typhoid fever in Bellevue Hospital. Baths are used for high temperature. Pure water is allowed *ad libitum*. Pure milk—peptonized in some cases—is diluted with lime water (one part lime water to three parts milk) and given every three hours. In the intervals other concentrated liquid nourishment (such as expressed beef juice, whites of raw eggs in boiled water, with a little brandy or liquid peptonoids) is given. The patient's wants are promptly attended to. A bedsore is regarded as a blunder rather than as a complication, and, notwithstanding the wretched condition in which some of the men were received, it occurred in but one desperate and protracted case. It may be of interest to mention that the use of bovinine topically seemed greatly to accelerate the healing of this bedsore and to destroy its odor and promote separation of its slough. Drugs in typhoid cases were used only to meet symptomatic indications. Our usual method of tubbing according to the Brand method was inapplicable to nearly all of the cases admitted, because they reached us late in the disease and in wretched physical condition; but sheet baths, bed baths, and even cold sponging with frictions contributed greatly to the comfort of the men, to the reduction of high temperature, and to final recovery. Two soldiers had moderate intestinal hemorrhage. They were treated by withholding food and drink for a time, small pieces of ice being allowed to dissolve in the mouth to quench thirst. In addition, the ice coil was applied to the abdomen, rectal enemata of four ounces of iced water were given, opium was administered hypodermatically in sufficient doses to get drowsiness and contracted pupils, ergotin was also given by the needle, and both patients recovered.

Age of Parents, and its Influence on their Progeny.—As the result of a careful investigation of twenty-four thousand cases, Dr. Jarosie presented to the director of the Hungarian bureau of statistics the following conclusions: The offspring of parents between the ages of twenty and twenty-five are likely to be weak and delicate, but between twenty-five and forty-five will probably be strong and thrive. The mother bears most robust children between her twenty-fifth and thirty-fifth year. When the mother is ten years younger than the father, the proportion of healthy children is greatest, the chances being ten per cent. more favorable than when the parents are of about the same age.

SOME REMARKS ON THE MIDWIFERY QUESTION—MUST THE MIDWIFE PERISH?[1]

By THOMAS J. HILLIS, M.D.
NEW YORK.

The influence of the midwife on the practice of medicine has received a large share of the attention of the profession for the past year. One would hardly think that this unobtrusive old lady would be the cause of such fuss and excitement, but such is the fact, and she is now discussed *pro* and *con.* in and out of medical societies—her individuality, her methods, and her prospects for the future.

From this shaking up it would appear that the great body of the medical fraternity has just awoke to realize that such an individual as she has only begun to exist, or is a thing of rapid pernicious growth. They seem to be unconscious of the fact that she was in existence and past grand mistress of her art in the days of the Pharaohs and long anterior to the lawgiver Moses, but are ready and able to believe that after the passage of a law and the stroke of a governor's pen she will receive her quietus and cease to exist as a disturbing element in the medical household.

We would have them remember that the customs and usages of a people for ages are not obliterated by the stroke of a governor's pen or by an act of Congress either. It is easier for a camel to go through the eye of a needle than it is to nullify the unwritten law of the usages of a nation; in fact, it may be said that these old customs and usages are a higher law, and one from which there is seldom any appeal. It is childish to assume that she can be erased and relegated to the shades of some purgatorial limbo for her shortcomings and her memory effaced from the monument she has built for herself in the hearts of the people.

The midwife can be found in every region of the habitable globe, barbarous and civilized alike. She has withstood the mutations of time and fortune for over five thousand years; she will withstand them until time is no more. She was called and anointed to fill an emergency and officiate when bashfulness or expediency demanded her presence, in preference to that of a physician, even though one was in waiting in the anteroom of the accouchement chamber.

Then we shall have to consider this prehistoric figure to-night, as of old, a part and parcel of the social fabric, as to destroy her would be to tear that fabric to pieces and bring about a condition of social chaos.

About that Magazine of Gun Cotton She Carries Concealed in her Skirts.—A great hubbub is now being made about the poor equipment and want of qualification of the midwife of to-day, and about the train of disease and disaster that follows in her wake. One thing, however, is certain, that she is an improvement on her sister of the past; though it must be admitted that, like all of us, she has a great deal to learn before she reaches the perfection mark that some would demand as a necessary adjunct of her calling.

Great stress is laid on a few isolated cases adroitly and hysterically told at the meetings of medical societies from time to time by good men and true, who think they have a mission to perform by opposing her, and who are animated by an honest desire to lay this old lady, the midwife, in the grave of her fathers; as, for instance, a dreadful and tragic event that could have been averted had the female in attendance been an intelligent and qualified person. The truth is simply this: that the exceptional cases told so artfully and well by interested parties only prove the rule, and

[1] Read at the meeting of the New York County Medical Association, June 20, 1898.

that rule is, that it is surprising how few fatal cases occur in midwifery practice, when we consider how widespread that practice is. For instance, about half the obstetric work of Greater New York is done by women, most of whom are ordinary midwives, a small fraction of whom are women doctors; the remainder, a goodly portion, is accomplished through the good offices of neighbors and janitresses, which latter often take the place of first assistants to the historic and much-abused midwife.

In the crowded tenement districts and flats this latter contingent, undergraduates of the midwife, take great pleasure in cheating the attending physician out of his fee, by not sending for him until too late, or by obstructing and badgering those interested in his coming. Their obstetric labors over, they immediately start in to abuse the physician, whom they intercepted, for his tardiness. After the physician has departed in disgust, often in a huff, the auxiliary and impromptu midwives compare notes, and finally compromise with the lying-in woman and other interested ones for a pint of beer, which is drunk with great gusto and many well wishes for the return of the same.

On the Mortality of Midwifery Practice.—Not more than one or one and one-fourth per cent. of the great multitude of lying-in women attended by midwives die in the puerperal condition, and it is doubtful if the services of trained physicians would materially alter these figures.

That He tempers the wind to the shorn lamb is a great truth, but not truer than that nature is kind to the puerperal woman in her simple and lowly condition, especially when surrounded by squalor and filth. Even handicapped thus, nature is loath to destroy her creation, and spreads a network of protection, woven with inimitable art, over the exposed surface; this network will prove a bulwark against disease if the seed of contagion has not been already sown by direct contact with the fingers of the attendant, be that attendant doctor, midwife, or janitress. No such disasters follow in the train of the midwife as we are told of so pathetically, so plaintively, by well-meaning but chicken-hearted gentlemen of our cloth, from this and other platforms.

As a rule, midwives get frightened early in a case, and often summon a physician when his services are not really required, as the case is a normal one and prognosis most hopeful.

For one stupid and incompetent midwife there are a hundred alert and active ones, who are quick to recognize danger and in time to summon medical aid. Indeed much more injury is done by meddlesome young physicians in pinfeathers, who are attachés, aides-de-camp, and supernumeraries of dispensaries and so-called lying-in asylums, with which unfortunately our city is weighed down.

These fledglings often invade a household as the parturient period draws near, and often two or three of them billet themselves on a wretched tenement for periods varying from six hours to four days; sometimes by relays they exceed this mark and sojourn for a week in the poverty-stricken hovel.

This perpetual vigil thus kept up by the enterprising young medicos in anticipation of a momentary accouchement is sometimes rudely broken, for it often happens that their anticipations are not realized. During this sojourn of the young physicians at the humble hostelry of the parturient woman, they make about three hundred vaginal examinations each, and generally succeed in congesting and drying up the parts and causing the woman much pain, often retarding labor for hours and raising the body temperature, thus unfitting her for the ordeal through which she must pass during her lying-in period; indeed, often jeopardizing if not destroying her life.

It appears that the objective point in these over-frequent examinations is the cervix, and the object to be attained the degree of dilatation of that cervix. A matter, too, of the highest importance to them is, what is the presenting part, and what the position of the head? This latter, though impossible at this early stage, is diagnosed with ease and accuracy by these medical wiseacres.

After dwelling in one of these abodes of misery for two or three days at a stretch, waiting and watching for an event that does not obligingly come off, the young disciples with some disgust pick up their belongings and hie themselves to their respective lodgings. It may be worth while to see what these belongings are; they consist of sometimes a change of clothing in a dressing-case and always of an immense gripsack stuffed to bursting with the very latest obstetrical outfit, where it is displayed conspicuously on a front table, that all may see and many wonder and guess of its contents. We will now open the bag thus conspicuously displayed, to find that the young physician provided for himself well in this, his enormous bag, and when he packed it took care to be prepared for all emergencies.

A few of the many things this immense bag contains are a rubber apron, a rubber sheet, a Kelly safety pad, a half-dozen Barnes cervical dilating-bags, an ether cone, a chloroform inhaler, a pair of baby scales, a quarter of a dozen perineum needles, two clamp forceps, two yards of iodoform gauze, one pound of absorbent cotton, a half a dozen two-inch and a quarter-dozen three-inch roller bandages, one tongue forceps, a quarter of a dozen scalpels, keen and shining, a symphyseotomy saw, a cephalotribe, a Tarnier forceps, a pair of non-fenestrated bull-dog forceps, a Lusk short forceps, a pelvimeter, and a full set of transfusion instruments. This, as hinted above, is only a small part of the contents of this remarkable bag, lugged into the sick-room by this young disciple of Æsculapius.

The writer of this article could relate sad reminiscences, reminiscences that would wring the hearts and cause tears to well up in the eyes of strong men, as a result of the meddlesomeness and bungling on the part of those young men playing at medical surgery by the grace and at the pleasure of dispensaries and lying-in asylums; indeed, very much more than he could of the midwife, though intimately acquainted with her methods for twenty years.

How her Departure from the Stage would Affect the Masses.—Now if the midwife was to make her exit from the stage to-night, what would the people gain by her demise and what legacy would she bequeath to us? What benefit would the people who have been accustomed to hear her voice, and shake her rugged hand, and pay her the small fee she asks for professional services—a fee, by the way, always in harmony with the surroundings and never exorbitant—derive from her taking off? They might gain little but lose considerable. The gain would be to force on a woman a man in the shape of a medical adviser whom she does not want; and in order to do this, a constable must be present in the sick-room, a thing as ridiculous as it is absurd for the man midwife. He could not hope to look for more reward than she generally paid to her old nurse and trusted friend, the midwife on her block, who in a poor family often helps in the cooking and in the direction of the household affairs, now left without a head for the time being. To force or push a doctor into the workingman's family when he is very well content with the service of the neighboring midwife is a form of servitude that he will not endure. He will repudiate it at the polls, the police court, and the chancel rail of his church; and however loud some of us of the medical guild

shout to him to desist from further engaging her services and hire one of us in her stead, he will pay no attention to that voice, but consider it a piece of insolence and an invasion of his rights not in consonance with democracy or with the spirit of American manhood.

True, the question will be asked: Have not the authorities power to make and enforce a law that will the better protect the people from the evil results and rash acts committed by ignorant midwives, whom they assume to be capable and hire as such, to attend their families in the important act of parturition? Yes, the authorities have power conferred on them by the people; but how this power is to be used is well defined, hedged in, and circumscribed. This is a question of great moment, but happily one easy of solution, from the fact that the actions of individuals become illegal only when they affect the rights and privileges of others, or when an individual is adjudged incompetent to take care of his affairs himself, as in case of imbecility, lunacy, or childhood.

None will claim, because a woman prefers a midwife to a physician to attend her in her confinement, that she has broken any law or done injustice to her neighbor by the invasion of any right conferred by Providence and the constitution. The woman who prefers the midwife up the street to the doctor across the way to wait on her in her accouchement may have chosen wisely and well, for two reasons: first, because the midwife attended her successfully in four previous confinements, she is right now to assume that this case also will be a success; second, the physician across the way charges twice the fee of her midwife for such professional services, and he does not wash the baby or the soiled clothes, neither does he prepare the noonday meal for her hungry husband when he runs from the factory on a half-hour leave of absence, to bolt his dinner in defiance of dyspepsia and the laws of health. Also she recollects a case the said physician had on the same floor where she lived last year. It was that of a young woman, kind and good, with whom she labored long and hard to employ her midwife in preference to that physician in her approaching labor. Other counsels, however, prevailed, and now the plaintive wails of a motherless child are echoing through the halls.

On the Legacy She Would Bequeath to Us.—It is hardly right to say a word on this subject, as the physician is popularly supposed to have no rights where the welfare and interests of the masses are concerned; still, nevertheless, a wise physician will halt to ask himself: Are my interests affected? What will I lose by the suppression of the midwife if I have to part with half my practice because the methods of the midwife are not agreeable to some of my professional brethren? Who will be the gainer by my loss? If the principal in the case, the parturient woman, is this gainer, why, I am satisfied to lose; but if somebody else and not she is the beneficiary, why should I lose my half to help the stranger to what is mine? Now, who is that stranger who will reap where I have sown? None other than the woman doctor, or what polite usage calls the lady physician.

This woman doctor has been creeping into the ranks of our learned profession, slowly but surely, for some time. Now it may be said right here that it is not the purpose of the author to quarrel with this woman or to criticise her in any manner, only so far as it directly affects the profession of which he is a member. Men, as a rule, are better adapted by nature and training for medical and especially surgical work than are women. This fact is so well recognized and established that nothing more need be said on this point. True, the new woman has entered the field and presented her credentials, but so far little notice has been taken of her or her passports. It will be noted that those who take pains to find out the real sentiment of that great heterogeneous mass called the public, the women of that public in particular, will discover that that sentiment is overwhelmingly against the pretensions and prospects of the woman doctor. They declare with one voice and loudly, "Let the midwife alone to pursue her useful but humble calling. As for the female doctor, we don't know her nor are we anxious to make her acquaintance, though some women's-rights women declare that she is the product of a higher civilization. However that may be, we want none of her; we have our midwives and our family physicians, whom we can call on when in need of their services. As for her, we repeat, we want none of her."

This sentiment is indeed widespread among the people, a thing that will throw a flood of light on the reason why the female doctor is making her way so slowly and meeting with such marked opposition in the practice of her profession, not from her male professional brothers, who, it may be said with some effort at blushing, are perfectly indifferent to her fate one way or the other, but from her own sex.

This will further establish the old saying, that a woman's worst enemy is a woman. If the woman doctor has met with success we will not begrudge that success to her; neither will we, if her efforts have been crowned with failure, cry our eyes out and sit in sackcloth and ashes bewailing her misfortune. As was said before, we are not overinterested about her, and certainly are indifferent to her success. Some physicians, however, believe the measure of her usefulness is filled when she qualifies as professional nurse, and that to step higher is only to insure her fall, embitter her life, and show the world that there are occupations that nature did not fit her for, and that one of these occupations is the practice of medicine.

About the Bashfulness of the Young Practitioner of To-Day Compared to Those of Olden Times.—Once upon a time it was the fashion for the accoucheur to conceal his obstetric outfit on his person, lest he alarm the already frightened woman whom he was called on to attend. This rule held good in the lowest as well as in the highest walks of life. Things have changed since then. Gates ajar! Shades of the illustrious dead, who have taught us to enter the lying-in chamber with bated breath and noiseless tread, behold, and stand aghast! the hippodroming and blowing of trumpets and unloading of nameless trumpery, called surgical appliances, hauled into the bed chamber and displayed with flourish under the very eyes of the woman who, anxious and pale, is now about to become a mother. The one who does all this is a young man just decorated with an honorary title, of great self-assertion and pompous of mien, who has just returned from an extra course in obstetrics at the famous school of Professor Sandyhill, of Edinburgh, after winning high honors for skill in gynæcology at the noted school of Professor Outerhaussen, of Zurich. With all his qualifications—and they are many, for though in years he is twenty-one, in learning he is profound—he is yet woefully deficient in tact and decidedly lacking in respect for the patient to whom he came to render aid; to say nothing of the good manners that prompted him to make a curiosity shop of her humble boudoir for the exhibition of the several trumperies called obstetric outfit, with which his bag is filled to the bursting-point.

The poor woman whom he came to succor may well exclaim in her travail, "Save me from this learned man; give me back my midwife, or indeed anybody whom I can trust!"

The Hardships the Demise of the Midwife will Bring to the General Practitioner.—Now since it

has been pointed out that the great mortality of midwifery practice exists only in the imagination of the alarmists, and since it has been further pointed out who these alarmists are, we will proceed to consider what effect the suppression of the midwife will have on the practice of our beloved profession. It will first deprive some capable and honest women of the means of making a livelihood; indeed, in many cases, throw them on the tender mercies of the commissioner of charities. Second, it will deprive the poor honest man's wife of an attendant of her choice, for if she cannot have her midwife she will not have an inexperienced young physician, such as the lying-in hospitals and charity societies furnish, even if he took a post-graduate course on the planet Jupiter. Third, it will directly affect the general practitioner —in fact, kill him—in the tenement districts, for this reason: the accoucheur accustomed to be there is the midwife, who lives in the neighborhood, and who is in the habit of looking up to the practitioner in her vicinity as something of an oracle when medical advice is the thing to be sought for or the object to be aimed at. She promptly reports a difficult case to him, after which that case is his, she serving merely as nurse and only too eager to obey his every wish. The neighboring doctor and the midwife have a perfect understanding. She does not claim to be an M.D. If a prescription is to be written, he writes it; if a fee is to be obtained, he gets it. In the face of these facts, what do some of us purpose doing? Why, nothing less than destroy our benefactor, have her perish from the earth, that we may kindle into life and put into power another woman, who is working hard against us, and who will further increase her activity if only the opportunity offers.

Are we medical gentlemen of this assembly going to commit *felo de se* and hand over our families, as some would have us do the midwife, to city charity? I hardly think so. The physician who attended the liquor dealer's or the grocer's wife in her confinement is most likely to be the person summoned when the baby has a colic, or when the mother suffers from hemicrania or tic douloureux, be that person man or woman; and it is most likely to be a woman for two reasons: she can afford to work cheaper than the man, and she will.

This quality of cheapness will attract tradespeople in moderate circumstances and readily decide the choice, other things being equal. Again, the natural or assumed bashfulness of some women is to be considered, and as a matter of preference, if one cannot have her midwife, she will choose the lesser evil and employ the woman doctor rather than the young physician so skilled in his art.

Her prejudice against the female physician, confronted by such conditions as these, will die out; then she will adopt and install her as family physician, though Dr. Greatheart down the avenue has attended her husband and children for two years with marked success.

We all of us know how fickle the public is; how a chance acquaintance or the turn of the dice will sometimes decide what physician will preside over the household.

Whose Side to Take in the War Now Declared.—The parturient act is a physiological one, and easily accomplished under normal conditions. If obstruction exists, which happily seldom does, the woman doctor too must summon aid, which is, as a rule, one of her own sex; but remember, she is not quite so quick to take fright and summon help as her stepsister, the midwife, whom she repudiates on professional and other grounds.

By thus suppressing the midwife we open wide the gates to our professional sisters and flood the whole country with female doctors. Practically, we hand this individual over the family practice, for between her and the specialist, whom she greatly admires, there will be no room for the general practitioner; he will get squeezed between the millstones.

After the dawn of this new day—the demise of the midwife—the woman doctor will claim her heritage, and that heritage will be everything in sight; and she will combat every influence that would prevent her from occupying her possessions.

Now what shall we do with the midwife? On whose side shall we range ourselves in the war waged against her? Of course we will be found on the side of right and justice, and at the same time pursue a course that will further enhance us in the eyes of that midwife, while throwing a more efficient covering of protection around the parturient woman.

Each physician can constitute himself a teacher and place himself in communication with the midwife in his immediate vicinity, who will receive him as a friend and listen eagerly to his advice. She will sit at the feet of her Gamaliel and hearken to his admonitions on things pertaining to the art of obstetrics.

Let this course be pursued, and there will be no upheaval, no breaking down of barriers, no tearing away of old landmarks, and no invasions of the rights of others. Let this course of instruction go on until the midwife is not only skilled in the handling of simple cases, but a keen and discerning judge of the conditions that surround and the means to be employed in order to bring the most difficult case of obstetrics to a successful conclusion.

Then let us look kindly on the midwife. She is a grand old figure; she looms up conspicuously through the ages, a figure much more picturesque than we, though we take pride in boasting of our achievements and our antiquity. Take it for granted that she has done some harm, yet she has not done a tithe as much as the medical alarmists would have us believe; nor is she at this moment doing half the injury the young medical gentleman is who takes pleasure in adjusting a Tarnier forceps for high delivery in a normal pelvis, and who has no scruple in using a symphyseotomy saw when the pelvimeter indicates a slight variation from the normal, and who immediately sets about tinkering up the perineum after the fashion of a housewife patching a quilt or a tinsmith soldering a leaky household utensil.

In the face of the facts adduced, let us reflect, and take care to remove the beam from our own eye before looking for the mote in the optic of the poor, simple, unobtrusive midwife.

51 Charleton Street.

An Easy Method for the Removal of Foreign Bodies from the Nasal Cavity of Children.—According to Dr. G. Bieser the employment of the usual methods for removing foreign bodies from the nasal cavities in struggling children and without anæsthesia is attended not only with the dangers from traumatism, but also with difficulty and occasional failure. The employment of aero-dynamics may overcome these objections. The method advised by the author is as follows: The child is placed in the ordinary position for intubation, the assistant holding his hand snugly over the child's mouth; one end of a piece of rubber tubing is snugly inserted in the nostril opposite the one holding the foreign body, the other end is inserted into the operator's mouth; the operator then blows suddenly and vigorously into the nostril and dislodges the offending body. The simplicity, cleanliness, and efficiency of this method are apparent; the child's struggles causing no traumatism.—*Pediatrics*, July 15th.

THE TECHNIQUE OF CLOSING CÆCAL FISTULA.

BY CARL BECK, M.D.,

NEW YORK.

In this era of surgical activity it was to be expected that fecal fistulæ, as sequelæ of appendectomy, should be met with much more frequently than a decade ago. Fortunately their tendency to spontaneous obliteration

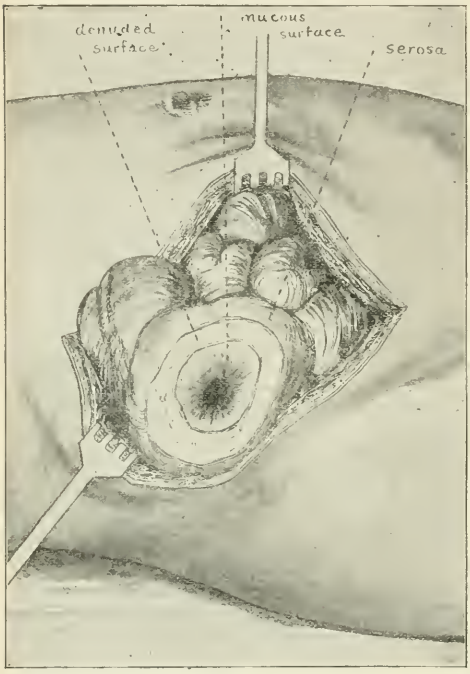

FIG. 1.

is considerable, so that with but few exceptions they close without demanding a secondary operation. But in cases in which the presence of multiple abscesses or gangrene of the walls of the cæcum has caused an extensive loss of substance, obliteration can be attained only by plastic operation.

It is obvious that such operations should consist in the direct plastic closure of the intestinal defect as well as of the opening in the integument. But the recent literature of the subject shows so many failures of this most natural and obvious method that some eminent surgeons advise abandoning it entirely, resorting finally to various kinds of entero-anastomosis. While I fully realize the difficulties of direct approximation, I do not believe them to be insurmountable, since I have succeeded in obtaining direct union in three cases in which the circumstances were not at all favorable.

In considering the technical points involved, it seemed to me that some of them were not appreciated as much as seems to be necessary. These points are thorough preparation, most extensive separation of the adherent intestine, care for a sufficiently large wound surface of the margins of the intestinal opening, straight-cut wound margins, and last, but not least, a simple but minutely applied continuous catgut suture.

The most thorough aseptic precautions should of course be taken. The patient must be well fed until the day before operation, when the intestinal canal should be well evacuated and the stomach washed out. During the last forty-eight hours digitalis is administered, and during the last twenty-four hours, if the patient be very weak, saline infusions are also given. I employ the saline infusion prophylactically in all weak patients before capital operations. It is simply wonderful how such patients generally stand even a prolonged anæsthesia, it seldom being necessary to resort to stimulants either during the operation or after it. As weak patients are liable to collapse during operation, so that powerful stimulants are required, I do not see why the most powerful of all, the saline infusion, should not be administered beforehand, thus in all probability rendering the tedious procedure unnecessary during the operation.

The discharges coming from the fistulous opening cause excoriations of the integument (Fig. 4), which are advantageously treated with a paste consisting of salicylate of zinc. If they cannot be healed, they will thus at least be rendered clean and made less irritating.

No antiseptic drug is used during the operation. The intestinal canal, above as well as below the opening, is packed temporarily with large strips of aseptic gauze, secured by strings, which easily enable the surgeon to pull them out when the intestinal suturing is nearly completed. Thus the escape of any contaminating fluid from the bowel is prevented. A still safer and easier method of preventing infection from the bowel is the temporary closure of the opening by a continuous suture, but the infiltrated-wound margins generally render it impossible to carry this out before the intestine is completely liberated.

This is effected by first circumcising the edges of the fistula far from the opening, sacrificing as much infiltrated tissue as possible, and then freeing the intestine from the adherent integumental strips and cicatricial tissue to the extremest limit. By exercising patience and keeping the knife laterally as far from the intestine as possible, or simply turning the knife, so as not to impair its walls, such liberation can be successfully achieved for a long distance. Then, after the margins of the intestinal opening have been equalized, the protruding mucous membrane is seized with forceps, pulled out, and cut off. Thus a denuded surface is left (Fig. 1) which permits the necessary coaptation of broad surfaces. Broad surfaces are the *conditio sine qua non* for complete union. If the thinness of the cæcal walls and their alteration by the adhesions and by prolonged inflammatory processes are

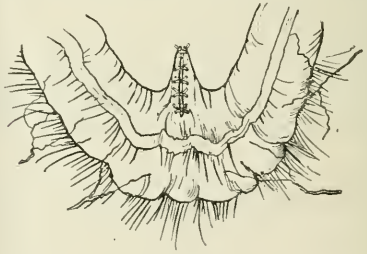

FIG. 2.

the main obstacle to immediate plastic closure, it is evident that by furnishing broad wound surfaces the chances of complete union are very much enhanced.

Extremely thin or much infiltrated portions of the intestine must be resected; then after the edges of the wound surfaces have been trimmed the intestinal walls consisting now of muscularis and serosa only, can be well approximated, so that they can be united by a double row of the continuous Czerny-Lembert suture.

First a deep row, closely touching the margin of the mucosa, but without stitching it, is to be applied; then a second row unites serosa and muscularis above (Fig. 2). After the completion of the sutures the mucosa must be coaptated well, although not sutured. The application of too many sutures should be

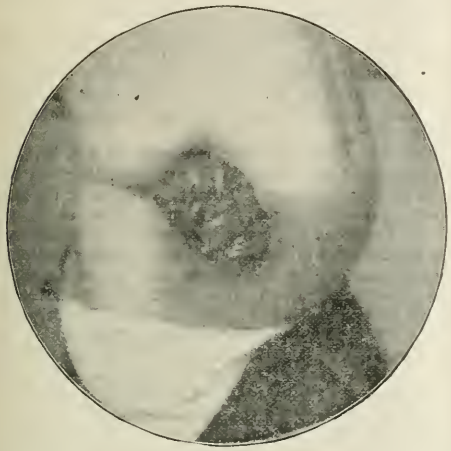

Fig. 2.

avoided, as the blood supply may become impaired and the agglutination thus become less secure.

The peritoneal edges are now to be united. This can be done only after extensive liberation, the tension sometimes being very great. If the tension persists, there will surely be separation of the wound margins. The muscular tissues and the integument are also carefully approximated, after the edges are trimmed in a suitable manner. It is advisable to unite muscles and integument rectangularly to the direction of the peritoneal row of sutures. It is understood that while these manipulations take place the neighboring intestines are protected extensively with sterile compresses.

For suture material I use the thinnest size of formalin catgut, the sterility of which after it has been boiled is indisputable.

Ice-cold milk, wine, and bouillon can be given a few hours after the operation. Opium and bismuth are administered to arrest peristalsis. Three days later soft-boiled eggs, meat, and farinaceous food may be permitted.

Case I.—A strong man, forty years of age, was taken sick January 15, 1896, with intense pain in the region of the umbilicus and of the right iliac fossa. Nausea and fever were also present. In spite of the gravity of the symptoms the patient walked about until January 29th, without consulting a physician. In a septic condition he was then admitted to St. Mark's Hospital. There were a small frequent pulse and high temperature; tumefaction and a corresponding dulness in the right iliac fossa were noted. The diagnosis was appendicitis perforativa. The operation, which was performed at once, revealed partial gangrene of the cæcum. There was a gray-yellowish pus of an offensive odor, but without a serous admixture. The appendix was not found. After the operation the patient recovered somewhat, but soon fell into a state of somnolence. Two days after the operation fæces appeared in the wound, defecation taking place now through the abdominal opening only. The temperature wavered constantly, and the pulse varied from 120 to 150. Repeatedly abscesses which formed near the cæcum between intestinal loops were opened. Then there was always slight temporary improvement, soon followed by the recurrence of septic symptoms, so that we gave the patient up at last. In the mean while an ectropion of the extent of the palm of the hand had formed (Fig. 3). Risking a last effort under ether anæsthesia, in exposing the upper wound margin I detected a small abscess which reached upward to the liver. After discharge of the abscess, the presence of which had not at all been suspected by me, the patient recovered rapidly, so that on March 20th I could proceed to the closure of the enormous ectropion. After having prepared the patient thoroughly for several days, and after having packed the afferent and deferent ostia prophylactically, I severed the intestine extensively from the adhesions, this being particularly difficult posteriorly. The freshened intestinal wound margins were adapted minutely and sewed up continuously, as described above. There was perfect union. The patient had defecated through the abdominal opening from the date of the operation on January 29th. After the enteroplasty he defecated by rectum. Only once, ten days after the last operation, fæces were found in the wound. On the following day perfect obliteration had taken place, and the patient has enjoyed the best of health ever since, except for the presence of a ventral hernia. After the separation of the intestine was perfected an intact appendix was discovered, which was slightly adherent to the peritoneum. Examination showed it to be normal. Therefore it may safely be assumed that originally there was a gangrenous process in the wall of the cæcum.

Case II.—A girl, twenty-four years of age, was admitted to St. Mark's Hospital, March 25, 1895, under the diagnosis of peritonitis. The history revealed that five days before she had been taken sick with pain in the right iliac fossa, fever, vomiting, etc. The pulse was small and frequent, the abdomen meteoristic, but in the right iliac fossa a well-marked dulness could be found on percussion. I immediately opened the abdomen, making an incision from above the symphysis to the anterior end of the eleventh rib. Gangrene of the appendix and of the cæcal portion adjacent to the base of the appendix was found. A large quantity of

Fig. 4.

thick yellow pus of strong fæcal odor was discharged. The tip of the appendix adhered to the tube, the swelling and dark red color of which indicated its direct participation in the inflammatory process. Some portions of the peritoneum showed a greenish discoloration. The intestine was covered with fibrinous membranes. A portion of the omentum, which had a

bluish-black appearance, was tied off and removed. Iodoform gauze packing. On the following day fæces were found in the wound. Later on all fæces passed through the abdominal opening. The patient recovered slowly, after it had repeatedly been necessary to open small abscesses in the immediate vicinity of the infiltrated margins. The patient suffered considerably from the excoriations of the skin (see Fig. 4), which did not yield to any medication.

On May 24, 1895, after thorough preparation, the infiltrated integument was resected in its entirety. Then the fistulous openings were sewed up and the adherent intestine was severed from its connections. The margins of the opening now having been equalized, and the protruding mucosa resected in the manner described above, the large flaps were united by two rows of sutures. Recovery was perfect. Aside from suffering from a small ventral hernia in the scar, the patient enjoys excellent health.

Case III.—A woman, sixty-four years of age, had been suffering from a large inguinal hernia for about thirty years, which became strangulated December 21, 1897. Unfortunately the patient did not submit to operation at once, so that peritonitis developed. When I opened the abdomen, December 24th, I found a large mass of intestinal loops in the hernial sac, among them the cæcum with an apparently healthy appendix. The ileum and cæcum were of a bluish-red color, and were covered with fibrinous membranes and bathed in dark serum of fæcal odor. In manipulation of the brittle intestine a rupture occurred. The vicinity had been well protected with compresses, so that the intestinal contents could escape without contaminating the abdominal cavity. After removal of the whole of the hernial sac and resection of the suspected portion of the intestine, the edges were united by Czerny-Lembert sutures. The patient recovered fairly well, but fæces appeared in the wound three days after operation. Soon an opening of more than half the size of that shown in Fig. 3 was formed, no more fæcal matter passing by rectum then. The patient suffered considerably from excoriations, which sometimes extended over the whole abdomen. On February 24th I closed the large fistula by first resecting the infiltrated margins and then liberating and sewing up the widely adherent intestine, in the same manner as described in Case II. The patient now enjoys perfect health, and there is no ventral hernia.

SCHLEICH'S GENERAL ANÆSTHESIA NOT A SUCCESS.

By H. RODMAN, M.D.,

NEW YORK CITY,

LATE HOUSE SURGEON OF MOUNT SINAI HOSPITAL.

Soon after the Schleich method was introduced into this country from abroad, where it was reported to have met with such great success, it was decided to give it a fair and thorough trial in Mount Sinai Hospital, where I had the opportunity of carefully observing the administration of the above anæsthetic and of studying the effects of the same upon the general condition and well-being of the patient after operation.

Although comparatively recent, other hospitals in this city had published such very favorable results concerning the new anæsthetic and its safe administration that we began to use it, at first rather cautiously, but soon extensively—in fact, substituting it for ether and chloroform almost altogether.

Of the solutions employed, known as Nos. 1, 2, and 3, the last was used in the vast majority of cases; No. 2 being employed for patients with serious heart lesions, and No. 1 for children under ten years of age, usually.

The anæsthesia was conducted under the most favorable circumstances, the solutions being carefully prepared by our druggist and known to be chemically pure, and the anæsthetists were reliable and experienced men.

From personal observation of seven hundred cases, the report of which is entirely unprejudiced, I submit the following facts:

Firstly. (*a*) Regarding the mixture itself, the general consensus of patients is that it is not unpleasant to inhale, and those who have taken ether much prefer the former to the latter; on the other hand, the Schleich mixture does not possess this advantage over chloroform.

(*b*) The length of time required for the Schleich mixture is from fifteen to twenty minutes, rarely less and occasionally more. Ether requires about the same time; chloroform, from five to fifteen minutes.

(*c*) The mask employed is a serious disadvantage, as the Schleich mixture contains both ether and chloroform among other ingredients, and the mask must be so constructed as to allow sufficient inhalation of ether while diluting the chloroform sufficiently with air. The mask requires thorough saturation at the beginning of the anæsthesia, and the fluid often trickles down on the patient's face, causing severe burns, several of which I have noted; but this can probably be obviated with a suitable mechanical contrivance.

(*d*) The stage of excitement is less marked (though present) than with ether or chloroform, although occasionally pronounced; general relaxation is present to a greater degree than with ether.

(*e*) Irritation of the mucous membranes, especially of those lining the respiratory and alimentary tracts, during the administration of the anæsthetic is diminished with the Schleich mixture.

Secondly. During the administration of the Schleich mixture the reflexes are lost early, especially the conjunctival reflex, thereby depriving the anæsthetist of one of his most important safeguards. The patient's pulse remains slow throughout, and in the majority of cases which I have seen he assumes a generally cyanotic condition, respirations usually diminishing and the pupils being somewhat dilated. At this stage of the anæsthesia, if not carefully guarded against, general cyanosis increases, respirations become infrequent and shallow, the pulse loses quality, increasing in frequency, and the patient suddenly stops breathing, respiratory failure having ensued, and this without much warning of any kind. I have witnessed certainly half a dozen of such conditions, which included two operations for inguinal hernia, two general laparotomies, one operation for osteomyelitis of the femur, and one for hemorrhoids. In all these cases the face was markedly congested, the reflexes were absolutely absent, the hands and feet were perfectly blue and cold, but the pulse was always perceptible, though slow and feeble and at times intermittent. Artificial respiration was always resorted to, and respiratory and cardiac stimulants, such as strychnine, digitalis, atropine, and whiskey, were at once administered hypodermatically and per rectum. All of these patients, however, recovered after energetic measures were employed.

I must also mention the case of a man, fifty five years old, on whom an enucleation was being performed, whose previous health had been good, who had neither lung nor heart lesions, breathing regularly and slowly, who had taken his anæsthetic without any difficulty, and with an experienced anæsthetist at his head. Suddenly he ceased breathing, his countenance assuming a pale and waxy hue; his radial pulse was entirely imperceptible for two minutes at least, although his heart could be heard beating very slowly and feebly, about 15 to the minute. Another interest-

ing feature observed was that there was no hemorrhage whatever on removal of the eyeball, which was almost coincident with the collapse of the patient. The anæsthetic was, of course, immediately withdrawn, amyl nitrite was applied to the nostrils, and heart stimulants were injected; the chest, particularly the cardiac area, was vigorously pounded with towels dipped in cold solution, ether also being poured over the same region. The pulse thereupon slowly resumed its original character, but not before fifteen minutes had elapsed, and the patient began to breathe more frequently (no Magendie had been administered, either before or during the anæsthesia), and subsequently fully recovered from this attack. I have witnessed several cases of respiratory failure from ether and chloroform, but never cardiac, as this undoubtedly was. I am led to believe that the unconscious state approaches an extreme condition with the Schleich mixture—much more so than with ether or chloroform.

Thirdly. Direct after-effects. Patients gag and vomit to almost the same extent as with ether or chloroform, which is also contrary to what has been claimed for Schleich's mixture as an advantage. The discomfort after operation is quite as marked; it is rather the exception to note otherwise.

The period of awakening from the influence of the anæsthetic is not shortened with the Schleich mixture No. 3, as has been affirmed by some, who claimed that as soon as the operation was over and the anæsthetic removed but a few moments elapsed before full return to consciousness; this has seldom been the rule.

Fourthly. Effect upon the lungs and kidneys. We had long sought and earnestly prayed for an anæsthetic which would eliminate the dangers to these viscera subsequent to anæsthesia. Has the Schleich method obviated these dangers? Certainly not, as will be proven by the following:

Several of the patients developed bronchitis, which was followed by pneumonia in some instances. One in particular which I remember was that of a young woman who, the day after operation, developed broncho-pneumonia, which at the end of two weeks proved fatal. I have also observed several patients with conjunctivitis and rhinitis after Schleich anæsthesia.

Again, I have noted at least three instances in which the urine of the patient previous to operation was perfectly negative, and which after operation contained albumin and casts, proving thereby that the Schleich mixture must necessarily be an irritant to the kidney. The Schleich method has not obviated or lessened the above unfortunate results due to general anæsthesia.

From the foregoing remarks I must therefore conclude that Schleich's solution does not even maintain a position between ether and chloroform, as I was led to believe from the early series of cases, but must foot the others. It is certainly less free from danger than ether and even chloroform, in my experience. It produces the same baneful effects upon the lungs and kidneys, and is a marked respiratory and cardiac depressant. Whether this is due to chloroform in combination with the other ingredients or not, I cannot say, but certainly chloroform alone can be administered more scientifically and with greater exactness than when in solution with other elements, as it is in Schleich's mixture.

The only advantage of the Schleich mixture is its pleasant inhalation, although it is often disagreeable to the surgeon and the bystander. With ether this can be modified by preceding the ether inhalation with a few whiffs of chloroform.

It has been claimed that the Schleich mixture can be administered with safety in serious heart lesions. The incident I have mentioned above disproves this statement, and in a patient with a perfectly sound heart; whereas I have seen chloroform administered in severe cardiac disease without bad results.

I must also add that, owing to the above poor results, we are gradually withdrawing the Schleich mixture from the operating-field and returning to our old friend and standby—chloroform.

Since leaving the hospital, I have learned that the Schleich method has been practically abandoned, and one of our leading surgeons has pronounced it to be an utter failure; also, one of its strongest advocates on its introduction into this country is thoroughly disappointed with its results.

I feel that the foregoing remarks will be substantiated and strengthened by future experiences, and that the Schleich method will be relegated to where it belongs in the order of efficiency.

I am indebted to Dr. A. G. Gerster for kind permission to use the statistics upon which this article is based.

TUBERCULOSIS OF THE MAMMARY GLAND.

By C. C. WARDEN, M.D.,

NASHVILLE, TENN.

The comparative rarity of this disease, in both primary and secondary forms, in large measure accounts for the meagre literature on the subject, especially in text-books. Of late the reports of cases in the various journals have seemed to awaken more interest and should serve as an incentive to further study of this manifestation of tuberculosis. It is closely allied and quite similar clinically to tuberculous adenitis elsewhere in the body, but it differs from the latter in one most important respect, namely, in diagnosis, since we are obliged to differentiate this affection from the various mammary neoplasms.

An examination of the literature on the subject shows that there have been reported fifty-eight authentic cases, while twenty-three others are reported as of mammary tuberculosis but lack positive and conclusive proof.

The etiology of this disease is of considerable interest. From the record of cases it appears that 89.6 per cent. occur in females and 10.4 per cent. in males. This rather disproportionate ratio between males and females, one to fourteen or thereabouts, doubtless will not be found to remain constant, and from a comparative standpoint seems rather accidental than otherwise. The infrequency of functional activity of the male breast or its exposure to infection by unwholesome practices would seemingly limit the number of cases to those of secondary nature, or, if primary, produced generally through injury. The ratio of one to forty-two, existing in adenoma and carcinoma, will doubtless be found to apply more nearly to tuberculosis, when there are more cases from which to draw deductions. The disease is most common between the ages of twenty and thirty-five, during a period when menstruation and glandular activity are thoroughly established. Cases have occurred before and after the menstrual life of patients. Roswell Park reports a case in a girl of twelve. The diagnosis was made by exclusion and the disease was supposed to be secondary. My own case occurred in a woman over forty years of age, whose menstrual activity had ceased. The number of patients who have borne children is somewhat over one-half. Persons of tuberculous tendencies are of course more prone to the disease. Davis and others report cases that originated during pregnancy. Mammary tuberculosis may be primary, depending upon infection through the milk ducts or through fissured nipples; or secondary, the disease

extending from contiguous foci of infection in the chest, ribs, or pleura, or through the lymph channels and blood supply.

Pathologically considered, the disease presents several interesting features. The axillary lymphatics are enlarged in three-fourths of all secondary cases and are frequently the site of the first manifestations of infection. In other instances axillary involvement may be apparently absent. Frequently a chain of enlarged lymphatics running from a nodule in the breast into the axilla can be easily demonstrated and occasionally the cervical glands also are affected. The terms discrete and confluent, applied by some writers, seem to be somewhat useless as pathological classifications; the tendency is most frequently toward a confluent condition, depending upon the length of time the infection has run. There have been instances in which adenomata, some taking on carcinomatous changes, have become tuberculous. The microscope will serve to establish the identity of the disease and will demonstrate tubercle bacilli either in the pus or in sections taken from the growth. The usual microscopic appearances of tuberculosis in gland substance are to be seen. We find typical tubercles with accompanying round-celled infiltration, epithelioid and giant cells with bacilli in them and in the connective tissue. There usually exists extensive proliferation of connective-tissue corpuscles. The common evidences of caseation, softening, and liquefaction are always to be found, though frequently quite late in the course of the disease. In many cases a period of five or six years may elapse before the occurrence of such changes, though usually a shorter time suffices. Secondary infection is common and various forms of pyogenic cocci are to be found in the discharges. There is a marked tendency toward the formation of obstinate fistulæ, particularly when the breast has been allowed to drain itself.

The symptoms are pain and tumor. In nearly all cases pain is a marked characteristic, and instances of painless tuberculous mastitis are very rare. Shattuck's case is one of these. His patient was a young unmarried woman who carried a painless nodule on her breast for six years, at the end of which time the growth was removed and found to be tuberculous. The pain is described as being sharp and lancinating and radiating to the arm, but more or less spasmodic. Usually pain is the first indication of the disease. A feeling of discomfort is produced by the patient's clothing, and there is a constant sense of uneasiness and weight in the gland. The breast is extremely sensitive to pressure. The tumor may consist of one or more nodules, firm, hard, and freely movable with the gland. The axillary lymphatics may or may not be enlarged. The skin may be freely movable over the growth but frequently is attached. It may be red or mottled in appearance, particularly in the later stages when softening is taking place. The nipple may or may not be retracted. Occasionally the entire breast becomes involved in one large nodular, unyielding, brawny mass, but as a rule the process is confined to the nipple area or some particular quadrant, generally in such cases the upper and inner, where the process extends from foci in the axillary lymphatics.

The diagnosis is usually difficult. Its importance should not be underestimated. The question becomes a most important one in women between the ages of thirty and forty, when the differentiation between tuberculosis and carcinoma is imperative. Under certain conditions it becomes impossible to distinguish them clinically, so similar are the leading characteristics. There is scarcely any disease of the breast with tumor with which this condition may not be confounded, be the case one of chronic inflammation, gumma, cyst, cancer, sarcoma, etc. Infallible means of differentiation are the microscope and bacteriological culture, which will clear up the diagnosis, no matter how complicated or perplexing the case may be under less exact methods of examination. The leading points of differentiation need not, therefore, be mentioned. When fistulæ already exist, the diagnosis is simplified. When softening can be detected, it is always well to aspirate, even when the nature of the disease is reasonably assured, in order that the diagnosis may be confirmed.

The prognosis in cases of primary involvement with or without axillary enlargements is good. In cases in which the growth is secondary the prognosis depends upon the amenability to treatment or removal of the primary source. The dangers of operative measures are slight when the general health of the patient is not seriously impaired.

The treatment consists in the entire removal of the gland, together with a wide margin of skin and all axillary lymphatics, when it can be demonstrated that they are involved. It may be difficult to convince the patient that such radical measures are necessary, particularly when she is assured that the disease is not cancerous. It is always well, consequently, to lay considerable stress on the danger of allowing tuberculous processes to continue. In primary tuberculosis of the gland it may suffice in some instances to incise and drain all suppurating foci and thoroughly curette the walls of the abscess cavities. Particularly will this treatment well apply in cases in which there is no apparent axillary involvement. This method should always be secondary, however, to a radical operation when it will be allowed. In the secondary variety of the disease the surgeon must decide how much operative interference the patient will be able to endure. The primary seat of trouble may be in the lung, and in such cases the removal or mere incision of the breast, even for the relief of pain, must depend on the strength of the patient and the length of time the original focus has been active. In weak or young patients palliative measures may be tried and the breast treated by applications containing resorcin or ichthyol, with perhaps belladonna or opium for the relief of pain.

The following is a case of primary mammary tuberculosis:

Mrs. T——, Scandinavian, forty-one years of age, widow; family history entirely negative. She was married at the age of twenty-five. She has always been in good health and regular in habits and functions. Her height is five feet and two inches; weight, about one hundred and twenty-five pounds. She was slightly anæmic but well nourished. She has four living and healthy children. Her husband, a man of good health from all reports, was accidentally killed in the spring of 1896, six weeks before the birth of her last child. A few months previous to her last conception there had been considerable irregularity in menstruation, with amenorrhœa at times. She carried her child to full term and had an easy and normal labor. She has not menstruated since. Her baby was weaned in January, 1897. She has nursed her children, using both breasts, in which there was always a full supply of milk until her third child was born in April, 1895. At this time the right nipple became sore and she noticed a scarcity of milk and a general tenderness in the right breast. The nipple gradually became retracted and attempts to draw it out gave her considerable pain, so she abandoned the use of that breast altogether. The nipple has since remained retracted. At the birth of her last child the right breast was not used at all, there being no evidences of activity in the gland.

In January, 1897, eleven months after her last confinement, her attention was called to the right breast

by a slight feeling of soreness, and she discovered a sensitive lump about the size of a hazelnut in the upper and outer aspect of the gland. The lump was of slow growth and had attained no larger proportions by March, when she first consulted a physician. I saw the patient in April for the first time. In the inner aspect of the gland a second mass was felt, small, hard, and irregular in outline, movable with the gland, and not involving the overlying skin. A week later the growth had become further disseminated, involving the lower segment of the breast. Some small enlarged glands could be demonstrated in the axilla. She described the pain as being spasmodic in character, sharp and darting, radiating toward the arm, with a continuous sensation of uneasiness and weight, increased by tight apparel. A fortnight later the entire gland appeared to be affected and the overlying skin had assumed a red, mottled appearance, and was attached to the growth in various places. The malignancy of the growth was not doubted, and an operation was advised and accepted. All appearances indicated that, whatever the nature of the trouble, the removal of the breast was necessary. On May 1st, the patient was prepared for operation. It was observed that in three or four places the growth had softened and fluctuation could be detected. Exploratory incisions were made in the softened tissues and about an ounce of pus and considerable cheesy débris were evacuated. The walls of the abscesses were thoroughly curetted. These walls presented a peculiar appearance. They were pearly white, quite anæmic, and of a decided resistance and density to the touch. The knife penetrated with difficulty, yielding a sensation as if it were passing through cartilages. A portion of this tissue together with a sample of pus was sent to Dr. A. S. Warthin at the University of Michigan for examination, who reported the case to be one of mammary tuberculosis. The tissue bore no resemblance to breast tissue, so thoroughly had the morbid process crowded out the gland structures. The patient improved immediately after these tentative operative measures. The relief from pain was complete, and in two weeks' time she was discharged. The incisions had healed, though there was considerable induration still existing in various portions of the gland.

The patient was again seen at the end of August. She looked much better and had better color. She ate and slept well. The breast gave no trouble and was not sensitive to touch or pressure of her garments. On examination no enlarged axillary glands could be detected. The breast itself was smaller than its fellow, but of normal consistence. The cicatrices alone were a trifle dense.

The patient has reported to me in August, 1898, just one year later, that she is perfectly well, and has had no trouble in her breast since it healed.

SOME OF THE SPECIAL GERMS IN INFLAMMATION OF THE MIDDLE EAR, WITH AN INTERESTING CASE.[1]

By WILLIAM CHEATHAM, M.D.,
LOUISVILLE, KY.

It is my purpose in this short paper to refer to the less common germs found in suppurative inflammation of the middle ear, mentioning only casually the more common ones, the streptococci, staphylococci, etc. Of course, in diphtheritic inflammation of the middle ear, the presence of the Klebs-Loeffler organism can be demonstrated; this form of inflammation may be either primary or secondary. If we have tuberculosis of the middle ear the bacillus can be demonstrated. The insidiousness of middle-ear trouble from this cause is one of its chief symptoms, as it is in such involvement in other parts of the body, since "freedom from reaction is possessed by the phthisical organism." Some say the diagnosis can be made by this symptom, and the location and appearance of the perforation. The possibility of a primary tuberculosis of the middle ear indicates the importance of bacteriological investigation.

In ten cases investigated by Milligan,[2] eight, or eighty per cent., were tuberculous. Buck[3] gives three common symptoms of tuberculosis of the middle ear: first, the tendency to localize itself in the vicinity of the upper and posterior portion of the membrana tympani; second, the marked insignificance of the pain, or even its entire absence; third, the intolerance of any but the simplest and gentlest local remedial measures.

Field[4] says: "The specific organisms of scarlatina and measles are occasionally, but not invariably, to be found when these respective diseases are complicated with aural discharges."

Roher asserts that in non-fetid discharges cocci alone are found, but in fetid discharges bacilli and cocci are found together; however, fœtor is not necessary to dangerous sequelæ.

Zaufal and others say that in otitis media acuta, due to cold and catarrhal extension from the nasopharynx, the pneumo-bacillus of Friedländer and the diplococcus of Fränkel play an important part. The bacillus of Friedländer has lately excited much discussion. The following extract concerning it is taken from the editorial of *The Journal of the American Medical Association* of April 23, 1898:

"**The Bacillus Mucosus Capsulatus (Bacillus of Friedländer).**—Since the first description by Friedländer in 1883, and by Weichselbaum three years later, of an organism which was first called a coccus (pneumococcus of Friedländer) and later regarded as a bacillus, occurring in acute fibrinous or croupous pneumonia, this bacillus has been found by many observers in various inflammatory processes in the lungs and other organs. As specific characteristics of this organism were pointed out its raised mucus-like growth on agar and blood serum, its nail-shaped growth on gelatin, its yellowish-gray growth with gas formation on potato, its failure to coagulate milk, absence of indol reaction, and decolorization by Gram's method of staining. It was generally found to be constantly pathogenic for mice, variably so for guinea-pigs (fatal in about one-half of the cases), rabbits, and pigeons; and, finally, its polymorphism and capsule formation were regarded as quite specific. From time to time bacilli differing in some respects from the foregoing description have been met with in pneumo-

[1] Read before the Mitchell District Medical Society, West Baden, Ind., July 21, 1898.
[2] British Medical Journal, November 16, 1895.

[4] Page 219.

nia and other affections, especially in inflammations of the middle ear and upper air passages, as well as in the peritoneum, liver, kidneys, and bladder, and lately also in the accessory sinuses of the nose. For these reasons there have often appeared in recent literature descriptions of a new bacillus, pathogenic for man. Most of the authors have pointed out the striking similarity between these various organisms and the bacillus of Friedländer. More or less striking differences in growth and other characteristics have nevertheless been assigned as sufficient reasons for establishing new classes. Fricke has been able to collect from the literature twenty-two bacilli which resemble the bacilli of Friedländer. He points out the many identical features and includes them in one group, with that of Friedländer as the type. He proposes as a name for this group the bacillus mucosus capsulatus. He has found such organisms thirteen times, often mixed with pus cocci, in the tympanic cavities of thirty-two cases of otitis media, in one case in the antrum of Highmore, in ulcerative endocarditis, in the stools in seven cases of gastro-enteritis. He makes the differences in the pathogenic actions of these bacilli the basis for two groups. In the first group he places those bacilli that kill white mice after subcutaneous inoculation, and which have none or only a passive pathogenic action when inoculated into the abdominal cavity of guinea-pigs and rabbits. In the second group are included those forms that are not pathogenic for mice on subcutaneous inoculation. Most of these were pathogenic for guinea-pigs."

W. C. C. Pakes, in the *British Medical Journal*, gives the morphological characters exhibited by this bacillus of Friedländer in some cases of pharyngitis and tonsillitis, as follows: "(1) Non-motility. (2) Polymorphism. (3) Decoloration when stained by Gram's method. (4) The presence of a well-developed capsule, especially when taken from the heart blood of the inoculated mice after death. The cultural characters were as follows: (1) Whitish, semi-translucent, sticky growth in bouillon. (2) Aerobic and anaerobic growth in gelatin, causing no liquefaction. (3) Whitish, moist, raised growth on slanted gelatin, the growth slipping to the bottom of the tube after four or five days. (4) Abundant gas production in glucose-gelatin stroke cultivation. (5) Slimy and almost transparent growth on agar and blood serum. (6) Formation of acid in dilute lactose bouillon. (7) Coagulation of milk with an acid reaction (in four cases before the ninth day, in one case on the eleventh day). (8) Brownish abundant growth on potato."

In regard to its pathogenicity, Dr. Pakes says that "mice were inoculated at the root of the tail, with a small quantity of a young agar culture from each case. In two cases the mice were dead on the second morning; in the other three cases they were dead on the third morning. The typical capsulated bacilli were found in the heart blood and spleen of each mouse, and from the heart blood pure cultures were recovered."

Just here I wish to report a case of acute suppuration of both middle ears, the left resulting in attic trouble, the pus showing externally about on the level of the superior edge of the external auditory canal posteriorly. A free incision was made, and drainage established; the patient made a perfect recovery in several weeks. The point of interest in the case, however, was the presence of a pure culture of the diplococcus of Weichselbaum, the description of which is given in the accompanying letter of Dr. H. H. Koehler, who made the investigations. It will also be observed from this letter that the disease started as an acute tonsillitis, in which there was also a pure culture of this diplococcus.

"Louisville, Ky., January 19, 1898.

"*Dr. William Cheatham, Louisville, Ky.*

"My Dear Doctor: It affords me great pleasure to comply with your wish in reference to the bacteriological aspect of the case of B. I——. When I first saw the patient both tonsils were much enlarged, the follicles containing a thick cheesy material, some of which I inoculated upon the Loeffler blood-serum mixture for diphtheria bacilli. An examination of the resulting growth disclosed that the organism was a diplococcus and in a state of pure culture, none of the ordinary pus germs being present. Neither were there any Klebs-Loeffler bacilli to be seen at any time. It is very unusual to obtain a pure culture from throat secretions; doubly so to obtain one from a diplococcus.

"Further to isolate and reveal any possible contamination, I made a number of plate cultures, but each resulting colony proved again to be only the diplococci as first seen. The patient by this time having developed a severe otitis media, some of the pus from the ear was sown on the blood-serum mixture, with the result of obtaining once more a pure culture of diplococci.

"This diplococcus on further investigation proved to be beyond a doubt the diplococcus of pneumonia of Weichselbaum, the other names for the same being micrococcus of sputum septicæmia Fränkel; lancet-shaped micrococcus of Talamon; micrococcus pneumoniæ crouposæ Sternberg; streptococcus lanceolatus Pasteur. Gabbi, in 1889, obtained this coccus in pure culture from a case of tonsillitis. In otitis media it has occasionally been found—by Zaufal in six cases, by Levy and Shrader in three cases, by Metter in five cases. It has also been found in an arthritis complicating a pneumonia. This coccus is a facultative anaerobic, growing well on glycerin-agar, blood serum, and gelatin, which it does not liquefy. It is always seen in pairs or a chain of pairs, a distinct halo surrounding the two.

"There being but one organism present in this case, it is but reasonable to suppose it to be the cause of the inflammatory troubles. It is a frequent inhabitant of the healthy mouth, and at times contaminates to a slight extent other cultures made from throat material.

"In conclusion, I wish to emphasize that the diplococcus of pneumonia must not be confused with the so-called pneumococcus, from which it differs essentially. The pneumococcus is misnamed, it being the bacillus pneumoniæ of Flügge.

"Respectfully,

"Henry H. Koehler."

This report of Dr. Koehler's is certainly of much interest. From it and the investigation of Milligan and others, it would seem proper to examine more frequently than we do the secretions from suppurative inflammations of the middle ear, and especially in those cases in which we might suspect tuberculosis.

The Elimination of Morphine.—Morphine is eliminated chiefly by the bowels, to a small extent by the kidneys, and still more slightly with the saliva. The man who would use the stomach pump in a case of poisoning by hypodermic injection of morphine would, by most people, be set down as an ignoramus; but he would be right, for it has been shown experimentally that, when the drug is administered subcutaneously, much of it is eliminated by the stomach—in fact, by repeatedly washing out of the stomach, more than half the quantity injected may be recovered.—William Murrell, "A Manual of Pharmacology and Therapeutics," p. 297.

A PRACTICAL MODE OF ADMINISTERING IODINE HYPODERMICALLY IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

By CHARLES WILSON INGRAHAM, M.D.,
BINGHAMTON, N. Y.

The hypodermic administration of therapeutic agents insures the immediate and complete absorption of the remedies injected. Further than this, it insures the highest degree of therapeutic potency. Hypodermic medication is, in fact, a truly scientific procedure of a most practical and serviceable nature, and is applicable to the treatment of a large range of acute and chronic diseases.

It was at a comparatively recent date that hypodermic medication came into general use in the continued treatment of chronic diseases, but it has been shown that there is no disease or morbid condition in which it is of greater usefulness than in pulmonary tuberculosis. It is now six years since I became interested in the treatment of the disease by hypodermic medication, during which period I have devoted much of my time to this branch of practice, and it is the object of this article to set forth my experience therein. I have long since come to regard hypodermic medication as solving many of the difficulties attending the treatment of tuberculous diseases, and its value I hope to be able to prove to the satisfaction of my readers.

In the first place, hypodermic medication is superior from the fact that it relieves the stomach of the necessity of digesting the therapeutic agents, which otherwise must pass through the stomach and assimilative organs. It is well understood that tuberculous diseases have a peculiar degenerative effect upon the functions of the gastric organs, which renders them unable properly to digest and assimilate the common food products, upon which the nourishment of the body depends.

This constitutes one of the most important reasons why hypodermic medication should be employed in the treatment of tuberculosis. The maintenance of general nutrition is eminently important for success, and the physician must concentrate his best energies upon securing and maintaining this in the highest possible state of efficiency. There is no possibility of any treatment being permanently successful if, in consequence of its administration, the factors which sustain general nutrition must suffer. By reserving the gastric functions for the support of general nutrition, and securing the continued introduction of necessary therapeutic agents through other channels, we have accomplished much toward final success in the management of each and every individual case of tuberculous disease.

Next in importance in favor of hypodermic medication is the fact that remedial agents hypodermically administered are assimilated in a condition which insures their most powerful medicinal action.

My chief dependence in the treatment of tuberculosis is placed on the local and constitutional effect of iodine hypodermically administered with regularity. Iodine is too well known to require an extensive introduction here. It is a remedy which has been widely employed for generations, and as a valuable and generally useful antituberculous agent it is more easily underestimated than overestimated. Its effects upon the system when hypodermically administered, as compared to its effects when administered by the stomach, are far superior. Iodine, administered by the stomach, is very apt to induce more or less serious gastric irritation, which will prevent its continued use in the majority of tuberculous cases. Then, again, as before stated, its medicinal effect is very inferior, and the prompt and thorough antituberculous results observed following its hypodermic use are seldom seen when the remedy is administered by the stomach.

Without entering into the scientific details of the subject, I would state that, used in the incipient stages of tuberculosis, iodine, hypodermically administered, systematically and continuously, for a sufficient length of time and in proper dosage, will in the large majority of cases quickly bring the progress of the disease under safe control, and eventually, by its alterative and reconstructive effect upon the tissues and fluids of the body, bring about a permanent healing of the pulmonary or laryngeal lesions, as the case may be. I do not think that iodine exercises a direct antituberculous effect, but rather that its control over the tuberculous processes is brought about by a modification of the tissues and fluids of the body, especially of the glandular system; and secondarily, through its re-establishment of a condition of general and local nutrition, approaching, if not reaching, the normal.

I find that in some text-books it is claimed that iodine exercises a direct action in tuberculous cases, by removing effete material from the tissues and rendering them less favorable for the development of the tubercle bacilli. I have employed iodine alone and in combination, in oil solution and in alcohol solution, and during the past five years have used a compound of iodine expressed in the formula herein contained. Especially have I found oil of peppermint, or its derivative, menthol, of great value used hypodermically in oil solution in combination with iodine. I first used iodine and menthol separately, but for some time have used them in combination. The formula of the iodine compound, upon which I depend almost exclusively in the treatment of tuberculosis, is as follows:

℞	Iodine	gr. $\frac{1}{2}$
	Bromine	gr. $\frac{1}{14}$
	Phosphorus	gr. $\frac{1}{100}$
	Thymol	gr. $\frac{3}{8}$
	Menthol	gr. $\frac{3}{8}$
	Sterilized oil	ʒ i.

The commencing dose of the formula is fifteen minims, while the maximum daily dose is one fluid drachm. The injections are never given oftener than once daily.

As is well known, iodine is an agent of wide chemical affinity, and when menthol and thymol are brought into its presence a chemical reaction occurs which deprives the iodine of its characteristic irritating properties and renders its hypodermic injection practically painless; whereas, in its natural state, iodine, when injected under the skin, induces severe pain and after-soreness at the site of injection. This compounding of the iodine results in a cherry-colored and perfectly transparent solution.

It is important, in the preparation of this formula, that the highest degree of chemical purity should be secured, and it is equally important that the most thorough antiseptic precautions should be constantly observed. Rancidity of the oil used should be guarded against.

It is not generally understood that menthol and thymol are each nearly as powerful germicidal agents as carbolic acid, and while they respectively possess this important germicidal potency they are each ten times less poisonous than carbolic acid. Hence with this iodine compound a very powerful local and constitutional effect is secured from the menthol and thymol.

Another factor in favor of the use of menthol hypodermically is that it is eliminated to a considerable extent through the lungs, and the odor and taste of menthol are frequently noticeable to invalids for several hours following the administration of the daily injection.

The fact that menthol, hypodermically administered,

is principally excreted through the lungs, is of great importance when considered in relation to the treatment of pulmonary tuberculosis, and it is a fact which I believe has not been previously reported, although it has been shown that oil of peppermint, administered internally and by inhalation, exercises a very powerful antituberculous effect in pulmonary and laryngeal tuberculosis.

Concerning the administration of the injections, it will be necessary only to state that they are given principally in the shoulders, from which location, on account of a minimum of muscular activity, but little soreness develops.

On account of the non-irritating action of the fluid, very little trouble occurs at the site of the injections. Their effect is almost immediately apparent, and is first manifested in the checking of the tissue waste peculiar to tuberculous disease and in a consequent rapid gain in flesh. As a rule, a decisive gain in weight is noticeable during the first two or three weeks of treatment. This gain in flesh, which is an indication of returning general nutrition, continues in curable cases to the point of normal weight, and coincident with this improvement the distressing symptoms of the disease disappear. The fever and night sweating are among the first to vanish, showing a decisive effect upon the toxins of the disease. Expectoration is promoted, and irritating or unnecessary cough in this manner relieved.

In all cases I administer the most thoroughly nutritive remedies in connection with a nutritious and easily digested diet.

If the patient is properly managed as concerns exercise, occupation, and environments, and a suitable course of nutritive treatment is employed, together with the systematic hypodermic administration of the formula given above, a splendid percentage of recoveries will follow and the permanency of recovery will be equally satisfactory.

I will report one case of typical pulmonary tuberculosis, hypodermically treated with the iodine compound, which practically illustrates the method advised.

Case I.—Patient, a man about thirty-two years of age; occupation, farmer. The history showed that he had contracted a severe cold, from which he did not recover, and which subsequently developed into tuberculous disease of the lungs. He had been under very thorough general treatment, with little or no benefit, as the disease had continued with progressive loss in weight and strength. Examination of the chest showed a very limited movement, with contracted walls. Percussion gave dulness over the apices of both lungs, while on auscultation respiration of a bronchial character was heard over the areas of dulness, with more or less complete absence of the vesicular murmur. Crepitation was present throughout the affected areas.

The iodine-compound injections were begun in December, 1892, and continued until March of 1893. At the end of the first month the patient had made a very apparent gain both locally and constitutionally. The cough was much improved, and expectoration had diminished in quantity and in degree of purulence. The fever and night sweating were also diminished, and there was a noticeable gain in weight. When treatment was discontinued, the following March, the cough, fever, night sweating, and other symptoms had disappeared some weeks previously, and the patient had gained about twenty pounds, having reached his normal weight. During the course of treatment I had encouraged him to practise chest gymnastics, and his chest expansion had increased from two and one-half to five and one-half inches. Examinations of his chest made at the time treatment was discontinued, and likewise several months later, showed an absence of the tuberculous disease, with resumption of the normal functions throughout the formerly affected areas.

The patient, whom I have carefully kept sight of since discharging him from treatment, has remained strong and well in every respect, and there has been no return of symptoms of pulmonary disease.

August 12, 1898.

Progress of Medical Science.

Vomiting of Pregnancy.—Dr. Bacon concludes an article in the *American Journal of the Medical Sciences* for June as follows: (1) The abnormal irritability of the nervous system, including the vomiting centre, is to be allayed by keeping the patient in the horizontal position; by attention to the skin, bowels, and kidneys; rectal and, if necessary, hypodermic injections of salt solution being used. (2) The hysterical condition, which is so commonly found present, should be controlled by strengthening the will and influencing the dominant ideas of the patient. (3) All sources of peripheral irritation should be discovered and treated. (4) In extreme cases subcutaneous saline injections serve a threefold purpose: (*a*) diluting the blood and increasing vascular tension; (*b*) eliminating toxins through renal and intestinal emunctories; (*c*) furnishing two most important kinds of food. (5) Induction of abortion is never indicated. At a stage when it is safe and efficient it is not necessary, and in extreme cases it adds greatly to the danger, rarely stops the vomiting, and can be avoided by the use of artificial serum.

Production of Immunity.—Whatever method be used, the following points are now almost proved: (1) the immunizing substances are in all probability of a proteid nature; (2) sterilized cultures or filtrates deprived of their specific poisonous properties may have a marked power of producing immunity; (3) an inoculated animal is for a short time after inoculation more susceptible to an attack of the specific disease, but as soon as this stage of susceptibility has been passed the resistance is increased; (4) whatever specific bacteria are used, either in the virulent or the attenuated form, the aim is to produce a mild attack of the disease, as a result of which the animal is immune; (5) the period required for the acquisition of immunity is in this case much greater than when antitoxin blood serum is used, in which latter case a protective influence is recognized almost immediately, or, at any rate, in the course of a few hours; (6) it is found, however, that the immunity so produced (the passive immunity of Ehrlich) is more transient than that obtained by inoculation with microorganisms or their products; (7) the blood serum of naturally immune animals has not yet been proved capable of producing immunity when injected into susceptible animals.—Dr. German Sims Woodhead, Treves' "System of Surgery," vol. i., p. 23.

Influenza in Children.—Dr. L. Fuerst (*Deutsche Medizinal-Zeitung*) recommends salipyrin, to which he attributes almost specific action. To obtain good results it is of prime importance that salipyrin be given at once and in not too small doses. He generally prescribes for small children (up to five years) 0.25 *pro dosi* (four grains); older children (five to ten years) 0.5 *pro dosi* (eight grains); still older children (ten to fourteen years) 1 *pro dosi* (fifteen grains), to be given three times a day in hot tea. Generally, after two days it suffices to use it only twice a day, and with this he continues until three or four days after the beginning of convalescence, the child, all the while, being kept in bed.—*The Medical Bulletin.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 1, 1898.

SOME OF THE MEDICAL LESSONS OF THE WAR.

THE recent war has been productive of new and instructive lessons for the future. This is particularly the case in reference to the proper care of the sick and wounded, in which the medical profession of this country, for humanity's sake and for its own good name, has the deepest concern. The widespread criticism of the management of the medical department of the army, however justly based, has assumed the ominous proportions of a public scandal. Whoever is to blame, there is no doubting the fact that the sick soldier has been most outrageously neglected. No one doubts that there was great mismanagement somewhere and by some parties, who should be made responsible for the gross neglect of duty which occasioned the privation and suffering of the men who had a guaranteed right to expect the best of care. Unfortunately for the medical department of the army, as the matter concerns the care of the sick and wounded soldier, the surgeon-general has been compelled to bear the brunt of blame and has been kept busy in explaining why what appears to the public to have been his duty in the premises was not properly performed. While no attempt can be made now to forestall opinion in view of a pending inquiry, enough facts have been brought forth in the controversy to prove the necessity for an entire reorganization of the medical service.

There are certainly many circumstances extenuating the charges of culpable negligence which deserve to be suggestively considered in the light of necessary reforms. There is no doubt that red tape, lack of system, and conflict of authority have had very much to do with the results in question.

It would appear from the testimony of such as have been charged with neglect of duty that the army in Cuba was a mere picnic of undisciplined troops, without suitable supplies of food, medicines, or surgeons, and without a responsible executive head. It is claimed that ample provisions were made for emergencies in different lines, but when the need for them became urgent the means for help were not at hand. Why this difficulty was not obviated as soon as it was discovered is not yet satisfactorily explained.

There is no doubt that there was much difficulty experienced in the transportation of supplies, but why this was not remedied as soon as discovered is also an open question. The surgeon-general blames the quartermaster's department, and the latter in turn shifts the responsibility on the medical department. Whoever is responsible for this, the fact remains that many of the supplies not only failed to reach their destination, but were actually sent home unused by anybody, while hundreds suffered and died for want of them.

The lesson to be learned from this is that no opportunity should be afforded in the future for thus shifting respective responsibilities. If the medical department had control of its own transportation of supplies, the surgeon-general would have been left without any possible excuse for not performing an obvious duty. In a general sense it is only fair, when great responsibilities are thrust upon an officer of the army, that he should have the power to discharge them.

The lack of competent surgeons for any campaign should never again be an excuse for neglect of needful ministration to the inmates of camp and hospital. The greatest possible care should be exercised in the selection of such men. As it was, the surgeon-general has been forced into the anomalous position of complaining that many of the men, who were presumably selected by himself, were inexperienced and incompetent. A great deal of this inefficiency on the part of the volunteer and contract surgeons was due to the fact that they were not properly officered by the regular army surgeon, who is trained to executive duties and knows the value of discipline. It is certainly a reflection on the intelligence, skill, and training of the regular army surgeon that it should be found necessary to outrank him in so many instances by the appointment of civilian practitioners to important and responsible positions. If there is any criticism or suggestion to be made on this score of inexperience of the newly appointed volunteer surgeons, its main reason is that the regular army surgeon was left too much in the background. It needs no argument to prove that the man who has been trained all his professional life to field, camp, and hospital duties should be the one to control and direct the fresh recruit.

It has also been proven that there is very much yet to be learned in the matter of camp sanitation. If there is any doubt on this subject, we have but to study the frightful prevalence of typhoid fever in all the localities where the soldiers have been congregated. The only seeming chance for a soldier to be gazetted is when his name appears on the mortality list. The country has been full of such silently suffering heroes. Here also is manifested the necessity for the selection and sanitary control of such camps by the medical authorities of the army. It is charged, with abundant opportunities for reasonable proof, that most of these selections were the results of political jobbery. In view of the deplorable unsanitary condition of most of them, it is impossible to believe that any well-qualified medical officer could have been guilty of such ignorance and stupidity as to advise their occupation.

While it must be frankly acknowledged that when typhoid fever attacks any camp it is liable to spread, it must also be admitted that there is no chance whatever of keeping an epidemic within bounds when such

a shameful lack of sanitary precautions was everywhere evident. The whole system of camp sanitation requires to be reorganized. We are tired of hearing it was this or that man's fault. If there is no one who can be made responsible for this wrongdoing thus far, let us see to it in future that some regulations are made and enforced which shall make a repetition of many of the errors of the past war inexcusable and impossible.

THE INVESTIGATING-COMMITTEE AND THE CONDUCT OF THE WAR.

The committee appointed by President McKinley to investigate the war scandals of neglect of the sick and wounded soldier, has commenced its work by the formulation of some questions to be answered by the different heads of departments. Although these inquiries appear to cover a great deal of ground, they are in reality too general in their scope to be of any real value. Those referring to the medical department of the army are particularly open to the objection of being for the most part indirect in their aim and quite unpromising in their results. While there is a disposition on the part of the committee to make the examination as comprehensive and as thorough as the circumstances will admit, its powers are necessarily limited, not only by virtue of its appointment as a part of a political machine, but also from the fact that it can have nothing more than a nominal authority to summon witnesses and none whatever to administer oaths. It is easy to see how under such circumstances no examination can be thorough enough to yield any practical outcome of radical reform. Whatever the verdict may be, it will be of necessity incomplete. The only committee to try the case is one appointed by Congress, and one which can call even the President himself to account.

THE FLY AS A PROPAGATOR OF TYPHOID FEVER.

The study of the numerous epidemics of typhoid fever in our various camps has developed an unusual amount of interest in the widely varied etiological conditions associated with their development. Every practitioner throughout the country, for obviously good reasons, never tires of collecting new facts, of examining new theories of the disease, and of applying new preventive measures against its insidious spread. The prevalent theory that a contaminated water supply is the main source of infection hardly needs additional proofs of its tenability, but the numerous and indirect ways in which the microbe can enter the system through the alimentary canal have hardly received the attention which they deserve. With the broader views of the many and complex causative influences regulating the extension of the disease, there is hardly an end to the number of conjectures which may fit the possibilities of the case. In the light of such considerations, it would appear almost impossible for any one to escape an attack at some time or other, so long as he or she is in any kind of contact, directly or indirectly, with men and things. Infected milk and food supply, soiled clothing, unclean utensils, careless disposal of dejecta, bad drainage, unwashed hands of attendants, and even the otherwise innocent oysters are now the recognized and dreaded carriers of the widespread and almost omnipresent poison. When large numbers of fever cases are congregated in one spot, the difficulties of meeting the emergencies of the situation are proportional to the intricate and multiplied possibilities of circumventing them. Under such circumstances there is a geometrical expansiveness of increased possibilities acting and reacting upon each other in many and constantly varying directions. Although attempts have been made to prove that the poison can be conveyed through the air and enter the system by way of the respiratory apparatus, there is yet nothing demonstrated which tends to militate against the present theory of intestinal infection. It is not sufficient now to say that the fever was not due to microbic contamination of water or milk, or to the usual causes so well known and understood, but we must take into account all the probabilities of infection through other and more indirect media. Lately the ordinary house and field fly assumes a comparatively new rôle as a ready and plentiful distributor of the poisonous microbe. The recent observations made by the government bacteriologists in one of the Southern camps invests this part of the subject with an interest and importance which can scarcely be gainsaid. Although, so far as has yet been stated, the proofs that the fly can carry typhoid are not so demonstrable as is its ability to convey cholera infection, the analogy of relations between cause and effect is strikingly probable.

Dr. M. A. Veeder in a recent issue of the Medical Record has recorded some observations on the point at issue, which are of the greatest importance in settling any reasonable doubt on the subject. The experimenter in question proved that flies readily devoured the microbes in alvine evacuations and discharged them in their fæces and also carried them on their feet, infecting every article of food or drink with which they may come in contact. From all accounts there were abundant opportunities offered the government experts for demonstrating how this could be done in the camp under observation, as the flies were very plentiful and the open privy trenches were very near the food supply. From a logical point of view such observations are exceedingly valuable and deserve thoughtful consideration. The fly is a natural scavenger, which is capable of transferring wound poison from one patient to another, is charged with propagating yellow fever and cholera, and, being very much of a gypsy in its migratory tendencies, may be found to be the ever-ready disseminator of the typhoid poison when under other circumstances the cause of the fever in distant and isolated districts would be inexplicable.

The Onion is believed to be a wholesome and nerve-soothing artice of diet, and still a Harlem physician's domestic unrest, resulting in divorce proceedings, has been traced to this fragrant vegetable.

HUNTING ACCIDENTS.

The sad misfortune which has during the past week befallen a well-known physician of this city is being followed by similar accidents, such as one has come to look for in considerable numbers at this season of the year.

A hunter at Lake Placid has just mistaken for a deer and mortally wounded his brother-in-law, and it was but recently an Adirondack guide shot his son, after having shot another son the year before. The loss of life from these mishaps is so great each year in our Nothern and Eastern hunting districts that, while no intimation of intention, so far as we remember, has of recent years been suggested, the State of Maine last year felt called upon to ask its legislature to establish a penal clause against the carelessness which at times must exist.

To fire into bushes simply because they move seems at least somewhat unsportsmanlike, and where there is a possibility of other hunters being the innocent cause of the commotion too much care cannot be exercised. In Vermont as well it has been proposed to put up notices of warning in the woods and at railway stations, to restrain the overzeal of the inexperienced. This or other means of giving publicity to the matter may serve to reduce the much too large number of killed and wounded hunters.

News of the Week.

The Presence of Yellow Fever in the South is still causing some uneasiness in the minds of the people and great watchfulness on the part of the health authorities. On September 26th twenty-six cases of a mild type were discovered in Wilson, La. The source of the infection is unknown.

Transposition of Heart and other viscera necessitated the firing of five shots into his chest by a suicide in San Francisco on Sunday last.

Insanity in Great Britain.—According to the latest report of the commissioners in lunacy, the number of patients under treatment in the public insane asylums of Great Britain and Ireland on January 1st of the present year was greater by 2,607 than that on the same day of 1897, and by 5,526 than that on January 1, 1896. The average yearly increase during the past ten years was 1,933. These figures do not necessarily indicate that insanity is increasing, for the statistics are those of the inmates of public institutions, and show merely that there is an increasing tendency to send to asylums for careful treatment many cases which formerly would have been retained at home or in the workhouses. Many persons, also, who are suffering from senile dementia now become inmates of lunatic asylums, whereas formerly they were allowed to end their days in the public workhouses and were classed as paupers and not as lunatics.

The Accidental Shooting of the son of Dr. Andrew F. Currier, of this city, while hunting with his father in the Adirondacks during the past week, will call forth much sympathy from the doctor's many friends.

New York's Opportunity.—In a short time New York will reassume its former pre-eminence in the number of under-graduate students, for all the States are getting medical laws which demand a preliminary examination of a proper character, and the student will find it no easier to get a degree of M.D. or to enter upon the study of medicine elsewhere than is now the case in New York.—*The Post-Graduate.*

General Wood's Powers Enlarged.—The jurisdiction of Military Governor Wood, formerly colonel of the Rough Riders and before that a surgeon in the army, has been extended by President McKinley, until it now embraces the entire province of Santiago de Cuba.

Cigarettes in Syracuse.—A new ordinance in Syracuse requires cigarette dealers to pay a license fee of $25, and provides for the appointment of an inspector to prevent the sale of "impure" cigarettes—whatever that may mean.

Bicycling is recommended by an asylum superintendent in Scotland as useful in the treatment of some forms of lunacy. A clear case of *similia similibus curantur.*

Chewing-Gum Thrown Out. — In an interview granted to a reporter at Jacksonville on the occasion of his visit of inspection to the camp there, Surgeon-General Sternberg said that he should not be held responsible for the mistakes of all the officers under him, and yet he had been criticised for all that had happened. He said that every requisition that had come to his office for supplies had been promptly filled, and that he knew of but one item that had been cut from a requisition, and that was chewing-gum. His department had been ready to meet every demand, and if the supplies wanted had not been asked for it was not his fault.

Red Cross Work in Porto Rico.—According to a report from Mr. H. F. Barnes, Red Cross agent at Ponce, the American army in Porto Rico is now, and has been for weeks, entirely dependent upon the Red Cross for all of its hospital food supplies. The Spanish hospitals, he says, are well supplied with everything needful for the comfort of the sick. The number of sick among our troops on the island is about ten per cent. of the entire force. Most of the cases are of malaria, dysentery, and typhoid fever.

Obituary Notes.—Dr. Winthrop B. Hallock, of Cromwell, Conn., died of apoplexy in this city on September 24th. He was sixty-five years old, and was a graduate of the Long Island College Hospital Medical School in the class of 1864. He was formerly an acting assistant surgeon in the United States army.—Dr. John W. Detwiller, of Newport, R. I., died on September 26th, of appendicitis. He was forty-seven years of age, and was a graduate in medicine of the University of Pennsylvania in the class of 1873.—Dr. John F. Isom, of Cleveland, Ohio, died recently of heart disease. He was sixty-seven years old, and was a graduate of the medical department of the Western Reserve University in 1877.

Dr. Rush S. Huidekoper, professor at the New York College of Veterinary Surgeons, the author of some excellent veterinary manuals, lieutenant-colonel of volunteers, formerly medical director of the camp at Chickamauga, and more recently surgeon-in-chief of the American army in Porto Rico, has been relieved from duty and ordered to report to the surgeon-general. It would be interesting to know how a man—who is, it is true, a graduate of a medical college, but whose practice has been confined, of late years at least, to dogs and horses—came to be appointed to the medical corps of the United States army, and placed in authority over medical practitioners, both civil and military, of long experience and wide reputation.

Major Brown.—A correspondent writes that Major Brown, of Camp Wikoff, to whom we referred recently as one of the members of the medical corps of the regular army, is a surgeon of volunteers. While gladly correcting the error of statement, we have no apology to make to Major Brown, for the company with which we classed him is one that would do honor to any man.

Army Surgeons Prevented from Making an Autopsy.—A member of a Texas regiment stationed at Jacksonville died recently in hospital while under anæsthesia, and the report got out among his former comrades that he had died in consequence of ill-treatment. The surgeons were preparing to make an autopsy, when the captain of the company forbade them to do so and sent a detail of men to see that his orders were obeyed. A military commission of surgeons was finally appointed to investigate the cause of death, which was found in a cardiac lesion.

An Emergency Medical Corps. — The following plan for relieving the government from the necessity of employing acting assistant surgeons is proposed by *The Medical Examiner:* "That there be established by the government and at its expense, either in connection with an already established institution or as an independent college, a post-graduate course for the purpose of instruction in all those medical matters which bear upon the military or naval service; that the students of this government institution be selected from the brightest graduates of the established medical colleges; that during this post-graduate course the students, limited in number, be maintained at the expense of the government; that in addition to the regular curriculum they be instructed and drilled in military and naval technical matters, sufficiently to enable them to understand military and naval manœuvres; that at the end of the course, to those who can pass the necessary examination, a diploma shall be given which shall set forth the fact that they are qualified to act as surgeons in the army and navy without further examination. But this diploma shall not excuse from a further examination for promotion in the service from grade to grade. By virtue of this government diploma the holder must stand ready to serve his country as a surgeon at any time when he may be called upon, until he shall arrive at the age of forty-five years, but it does not prevent him from engaging in regular practice wherever he may elect."

Investigation of the War Department.—The commissioners appointed by the President to investigate the conduct of the war department, and to place if possible the responsibility for the unnecessary suffering and loss of life of the soldiers at Santiago and in camp at home, met at Washington on Saturday last. The medical member of the commission is Dr. Phineas S. Conner, of Cincinnati—Dr. Keen, of Philadelphia, who was first mentioned for the place, having been unable to serve. The departments to be specially investigated are the medical, the commissary, and the quartermaster's departments. The commission has no authority to compel the attendance of witnesses or to make those testify who have responded to the invitation to be present.

The Idaho State Medical Society held its sixth annual meeting at Moscow on Tuesday and Wednesday, September 6th and 7th. The election of officers resulted in the choice of the following to serve for the ensuing year: *President*, C. W. Shaff, Lewiston; *Vice-President*, E. F. Guyon, Montpelier; *Secretary*, Edward E. Maxey, Caldwell. The next annual meeting will be held at Lewiston, September 5 and 6, 1899.

Dr. Sternberg's Literary Activity.—In a recently published biographical sketch of the surgeon-general, we are told that he is the author of no less than one hundred and twenty-two journal articles in English and Spanish, and twenty-nine single works. This list does not include his many letters to lay and medical journals in reply to criticisms of the army medical department, written during the past three months.

Bellevue Hospital.—The following appointments have been made to the visiting staff of Bellevue Hospital: Dr. Henry C. Coe, gynæcologist; Dr. L. Bolton Bangs, genito-urinary surgeon; Dr. B. Farquhar Curtis, surgeon; Dr. George D. Stewart, surgeon; Dr. Egbert Le Fevre, physician.

The Death of Dr. J. E. H. Nichols.— A special meeting of the medical board was held at the Manhattan Eye and Ear Hospital, on September 13, 1898, to take action on the death of Dr. J. E. H. Nichols. The following resolutions were adopted:

"*Whereas*, We have heard with sorrow of the death of Dr. J. E. H. Nichols, in North Carolina; and

"*Whereas*, He has been connected with this institution for the past twelve years, the latter five of which as surgeon; therefore be it

"*Resolved*, That in the death of Dr. Nichols the hospital has lost one of its most efficient and faithful workers, and we, his colleagues, a loved and valued friend;

"*Resolved*, That the flag of the hospital be displayed at half mast until after his interment;

"*Resolved*, That we extend to his family our sincere sympathy in their sorrow;

"*Resolved*, That these resolutions be spread on the minutes of the medical board, and that a copy be sent to his family and published in the New York Medical Record and in the *New York Medical Journal.*

D. B. St. John Roosa, *President of the Medical Board;* Frank N. Lewis, *Secretary.*

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNÆCOLOGISTS.

Proceedings of the Eleventh Annual Meeting, Held in Pittsburg, Pa., September 20, 21, and 22, 1898.

First Day—September 20th.

The association met in the assembly hall of the Monongahela House, and was called to order by the president, Dr. Charlls A. L. Reed, of Cincinnati, Ohio, at 10 A.M.

Dr. John Milton Duff, of Pittsburg, welcomed the association on behalf of the local medical profession.

Lieut.-Gov. Walter Lyon followed with a brief but very eloquent address of welcome on behalf of the citizens of Pittsburg and of the State. President Reed, in behalf of the association, responded to these remarks of welcome in a very concise but graceful speech.

Following the preliminary exercises came the first paper of the scientific session, by Dr. Frederick Blume, of Allegheny, Pa., entitled

Some of the Complications following Vaginal Hystero-Salpingo-Oöphorectomy in Pelvic Suppuration, with Remarks on the Objections to this Operation.—He said that a perusal of the literature of the past few years proved that vaginal hysterectomy had made its way here and abroad. Its condemnation upon theoretical grounds had decidedly diminished. Its advantages were too plain to permit being longer ignored. Men who, in the beginning, strongly objected or opposed this mutilating operation, as some were fond of styling it, had changed their opinions. Guided by the experience of others, they had adopted this method and confirmed the assertions of its advocates that it was a conservative operation in the broadest sense of the word—a procedure which, though sacrificing the uterus, conserved the life of the patient even under circumstances in which the suprapubic route would mean certain death. The propriety of removing the uterus in suppurative disease of the appendages had been questioned ever since Péan introduced vaginal hysterectomy. Briefly stated, the chief objections were: (1) that the uterus was not a useless organ after the ablation of the appendages, and should not be sacrificed unless seriously diseased; (2) that vaginal hysterectomy was an incomplete procedure, was followed by serious complications, and was not curative. The disposition to preserve the uterus during the child-bearing age in women with healthy tubes and ovaries or in unilateral suppurative pelvic disease could well be understood, but why this organ should not be removed as the initial step of a life-saving operation, when the ablation of both appendages became a necessity, was beyond comprehension. The assertion that the uterus without the appendages was still an important organ, that its functions had not ceased with the artificial induction of the menopause, must be rejected as untenable in the light of present knowledge. The arguments that after the extirpation of the uterus the nervous phenomena were more pronounced than when the appendages were left alone, had strongly influenced many surgeons against vaginal hysterectomy. Careful investigations, however, had shown that these arguments could not be verified. Mainzer, in a report of two hundred vaginal hysterectomies for chronic inflammation of the adnexa, performed in Landau's clinic, had arrived at the conclusion that there was less disturbance of the nervous system after the radical operation than after salpingo-oöphorectomy alone. He further had stated that the age of the patient bore no relation to the presence or absence of these nervous symptoms. Dr. Blume did not confirm the view that the removal of the uterus increased the nervous disturbances incidental to the menopause, and he was inclined to believe that this view was based upon the complaints of neurotic women. As to the sexual passion, his patients, with but one exception, had stated that they had as much sexual appetite now as at any time before operation. Two of them, young widows, who married a year after the operation, informed him repeatedly that they were more passionate and enjoyed sexual intercourse more than ever. The mortality of vaginal hysterectomy was considerably less than that of the abdominal operation. There was, however, a diversity of opinion as to the ultimate results of the vaginal procedure. The essayist did not resort to the vaginal method in those cases in which there was a possibility of saving one tube and ovary; *i.e.*, in cases of unilateral suppuration, even when due to gonorrhœa. He was not yet convinced that both appendages must be sacrificed, far less the uterus, when gonorrhœal infection was limited to one tube and ovary. His personal experience with vaginal hysterectomy for pelvic suppuration was limited to forty-two cases operated upon during the years 1895 to September, 1898. This series, though small in number, was quite interesting, on account of the extent and the gravity of the pathological changes. Of the forty-two patients, eighteen belonged to that desperate class of cases which, if treated by the abdominal route, were either left unfinished or, according to the statements of prominent operators, had a death rate of from twenty-five to thirty per cent. in the hands of the most skilful surgeons. The pelvic organs were agglutinated into one mass, and could not be distinguished by vaginal or rectal examination. In some instances these masses reached half-way to the umbilicus; while in others the peritoneal cavity was less involved and they extended downward into the vagina, pushing the uterus against the symphysis pubis and compressing the rectum to such an extent that an ordinary rectal tube could not be passed without difficulty. The lesions of the remaining twenty-four patients were not quite so extensive, yet in every instance both appendages were so far involved that a conservative operation was out of question. Complications occurred in three cases.

Dr. Joseph Price, of Philadelphia, said that the sexual appetite of women, alluded to by the essayist, following a variety of operative procedures, was in many instances improved rather than impaired. It was rare for a woman to complain of impaired sexual appetite after a supravaginal hysterectomy. Age, however, should be considered in discussing the nervous phenomena incident to a normal or precipitate menopause. He advocated the abdominal route, saying that the vaginal method was an incomplete one. The latter method favored bowel obstruction. In ten vaginal hysterectomies performed by Coe in his early work, there were two deaths from intestinal obstruction.

Dr. Edwin Ricketts, of Cincinnati, cited an instructive case in which it became necessary to resort to the combined method. He spoke in favor of the vaginal route in some cases, but not in all instances, for pus in the pelvis.

Dr. Rufus B. Hall, of Cincinnati, was willing to admit that there were cases that could be dealt with by vaginal section and drainage, but the field for this operation was limited. In cases in which there were dense adhesions of viscera, good complete work could not be effected by the vagina. Experience had taught him that if a patient was under thirty-five and the uterus was removed by an abdominal operation and the cervix was left, she suffered less from reflex disturbances than she did when the uterus was left.

Dr. Charles Greene Cumston, of Boston, said

that suppurative conditions within the pelvis demanded different treatment, according to their situation, the number of foci, their size and nature; and the gynæcologist in making the diagnosis and considering the choice of operation should take account of all of these things, whether the case was suitable for the vaginal or for the abdominal route. In most cases of pus in the pelvis, considered in a broad sense, posterior colpotomy was a trifling operation, yet a conservative one. It could be performed in chronic purulent cases of the female pelvic organs and in acute suppurations in which it would be dangerous to do either abdominal or vaginal hysterectomy.

Dr. James F. W. Ross, of Toronto, said that at the Montreal meeting of the British Medical Association vaginal hysterectomy for cancer was discussed, and his experience agreed with that of Price, that this operation for carcinoma, no matter how early it was done, was not satisfactory. High amputation of the cervix after the method of Byrne had been satisfactory in his hands.

Dr. L. H. Dunning, of Indianapolis, remarked that the character of the suppurative products encountered by the surgeon called for different lines of procedure. In the cases described by the essayist, in which the pus accumulations were exceedingly large, extending as high as the umbilicus, fixed, and extending down into the vagina, it had been his practice for the last ten years, and he saw no reason to change it, to do vaginal section. In such instances, when vaginal hysterectomy was done it was exceedingly difficult, if not impossible, to remove the pus sac. He had operated by vaginal incision in fifty cases of the kind described. Of these patients, four returned for subsequent operation. All but one of them had made primary recoveries.

Dr. B. Sherwood Dunn, of Boston, believed that the perfection of the technique of hysterectomy by the vaginal route greatly exceeded in difficulty that by the abdomen. The complications following operation by the vaginal route exceeded those of operation by the abdominal method. The danger to the ureters and the bowel and postoperative hemorrhage were very much greater by the vaginal than they were by the abdominal route. He restricted vaginal hysterectomy to a few selected cases in which he was fearful of death of his patients if operated upon by the suprapubic route. The vaginal operation was difficult, and in many instances it had to be followed by a second operative procedure through the abdominal wall.

Dr. W. E. B. Davis, of Birmingham, held that vaginal incision and drainage had a large field. There was a great deal of difference between operating in old gonorrhœal cases and operating in fresh ones. Unquestionably all of the cases following the puerperal state, in which the surgeon could place his finger upon the side of or behind the uterus, could be dealt with better by the vaginal route. The surgeon made a mistake if he opened the abdomen to deal with this class of cases, when vaginal incision and drainage were such a simple procedure. While a few cases would return for secondary operations, the surgeon should be willing to give young women several operations, if necessary, to save important organs.

Dr. C. A. L. Reed, of Cincinnati, formerly resorted to the vaginal route, and, after trying it carefully and conscientiously in many cases, he had practically abandoned it and had returned to the abdominal incision. He had found, however, a class of cases in which hysterectomy was a very important concomitant in the course of treatment, but even in these he did not remove the uterus per vaginam.

The paper was further discussed by Drs. A. B. Miller, of Syracuse, and J. Henry Carstens, of Detroit.

Operative Technique for Intraligamentous Ovarian Cystomata.—Dr. D. Tod Gilliam, of Columbus, Ohio, contributed this paper. Prior to the enucleation method of Miner, the surgical treatment of these cases was crude and incomplete. Miner's method marked a new epoch and would ever remain the foundation principle of their surgical treatment. It was, however, attended with so much difficulty and danger as greatly to abridge its usefulness. The chief danger was from hemorrhage, which was oftentimes fearful and not infrequently fatal. Other and by no means unimportant dangers came from injuries to important pelvic structures inflicted during hurried and blind dissection. There was a crying need for something better. The essential factors of the ideal operation were: (1) tapping, to reduce the volume of the cyst and to open the way for hæmostasis and enucleation; (2) ligating the supply vessels to control hemorrhage; (3) enucleation along the line of cleavage to insure easy, rapid, and safe dissection. This technique was foreshadowed in a case in which the essayist operated on October 30, 1894. Here he gained his first knowledge of the line of cleavage for intraligamentous cyst, and reported it to the Columbus Academy of Medicine. In 1896 Kelly announced the line of cleavage for intraligamentous uterine fibroid. Hall (in 1897) was the first to combine all the essential factors of the ideal operation. Hall's method, however, included hysterectomy. The method of the essayist without hysterectomy was as follows: First tap the cyst and drain off its contents; then ligate the ovarian artery near the pelvic wall and place a clamp between the cyst wall and the uterus. Select a point as low down on the anterior wall as practicable, and with a pair of forceps lift up the capsule and make a small opening. Insinuate a finger and sweep it around, separating the cyst from its matrix at the base. Now turn the finger upward and work in the direction of least resistance, slitting the capsule as you go. This will indicate the line of cleavage and will generally run upward and outward diagonally across the face of the tumor. Now introduce the hand and strip off the capsule from below upward, following the line of cleavage. Enlarge the opening by making an incision parallel to the capsular margin; seize the cyst and roll it out of its bed, stripping it from the posterior capsular wall. Trim and suture as in other cases.

General Considerations on Septic Infection of Ovarian Cysts.—Dr. Charles Greene Cumston, of Boston, read this paper. Inoculation experiments had shown that if the liquid contents of an ovarian cyst were not contaminated by bacteria, they would remain aseptic and would undergo no change. But if, on the contrary, microbes attacked a cyst and entered it, its contents would serve as excellent culture media and symptoms of infection would soon appear. But the human organism would take on the offensive and would react against the bacteria which had infected the cyst; leucocytes came from the walls of the vessels and attacked the invading microbes, and thus we had the transformation into pus of the liquid contents. There were two kinds of septic infection of ovarian cysts, namely, pathogenic infection and saprophytic infection. Pathogenic and saprophytic organisms often entered ovarian cysts through puncture, incision, and drainage. As puncture was discarded in a great number of instances by the majority of the profession, it was clear that the patient contained the agent of the septic process under consideration. The germs did not come from without, but from the interior of the organism, and the process might be called a true auto-infection, which took place in one of three ways: (1) By means of the blood, in which case the infection was direct, produced by phlebitis, which extended up to the cyst; or it might be indirect, in which case the infective elements were carried in the gen-

eral circulation into the tumor by means of its pedicle. (2) Infection might take place by way of the lymphatics, in which case the lymphatic channels acted as the contaminating canals and allowed a direct introduction of the germs into the interior of the cyst up its hilum. (3) There might be infection through adhesions, which were plentifully supplied in new-formed vessels and which were intimately connected with those in the walls of the cysts, and thus allowed an easy transportation of the bacteria. After giving at considerable length the symptoms of ovarian cysts and dwelling upon the diagnosis and differential diagnosis, the author dealt with their operative treatment. Operation for the removal of ovarian cysts which were the seat of septic infection might be divided into four stages. The first was incision of the abdomen; the second, the breaking up of the adhesions and ligation of blood-vessels which they contained, and then the pus might be removed by trocar and not with the knife, because if the cyst was incised pus would immediately flow out and the wound would very likely become infected by the septic material. The third step in the operation was the extraction of the cyst through the wound, and in doing this the surgeon should be careful to avoid infecting the abdominal incision at the time he was drawing the pocket through, but this complication could be easily avoided if aseptic gauze sponges were tightly packed around and inside the line of incision. Next came the ligation of the pedicle and its section, after which it was dropped into the abdomen. The fourth step in the operation consisted in the cleansing of the peritoneum, which should be done with great care, especially when the operative field had run any chance of infection. If this had occurred, free irrigation of the peritoneum was proper, but it should be done with care and the liquid employed should be a warm decinormal salt solution. Care should be taken to limit the irrigation to the subumbilical portion of the peritoneal cavity, and a back flow of the liquid toward the diaphragm should be prevented by having the operating-table perfectly flat and the thorax slightly raised.

A Second Contribution to the Surgical Treatment of Intussusception in Infants, with Cases.—Dr. Henry Howitt, of Guelph, Ontario, read this paper. In the paper the term infant was restricted to those under one year of age. After briefly describing the different varieties of intussusception that occurred at any period of life, and also referring to particulars in regard to statistics, modes of growth, length of bowel involved, and the severity of attack in the varieties, he stated that in the infant we had only the acute forms with which to deal in practice; nay, possibly only the ileo-colic, which all authorities agreed to be the most acute and rapid variety of invagination. It was, he stated, the ileo-cæcal form plus the valve distended and the lumen occluded by the swollen and œdematous invaginated portion of the ileum which, owing to the tight constriction at the neck by the valve, in a manner resembled a well-hammered boiler rivet, that no evenly distributed pressure from within could force out. The author believed that many instances of the trouble occurred in infants, leading invariably to death, without the true nature of the malady being recognized by the attendant; and that when the facts having reference to this variety of intussusception became generally known, fewer deaths would be recorded in certain bowel affections and more lives saved by surgical means. He had seen seven cases, six of them almost within the past five years, or since his attention was drawn to the subject. Six were in male children; all came from a district the population of which was under twelve thousand. He had operated successfully on four, all of whom were under six months of age. A fellow-practitioner lost one, owing to an accident during operation. In one case the friends refused operation and death resulted, and one child died shortly after the onset, before anything could be done. The symptoms of ileo-colic intussusception were fully dwelt upon. In regard to its diagnosis, the speaker emphasized the importance of the history of the onset, and stated that without it the attendant might be likened to a ship in a storm without helm or compass. In fact, the nature of the onset might suffice for a diagnosis. The detection of a tumor in the course of the colon left no room for doubt. The condition in this form of intussusception was such as to preclude the hope of recovery by any method short of operation. No time should be lost in trying either bowel inflation or injection of fluids. They could do no good. His method of operating was as follows: He maintained the temperature of the child by suitable applications to the extremities and body during operation. Rigid aseptic preparations and precautions should be carried out. A median, three-inch incision, avoiding the high-placed bladder, was made; the small intestines were eventrated as rapidly as possible, and protected with gauze, which was irrigated with water of suitable temperature. The evisceration allowed the obstructed portion of intestine to be brought into view. When, as was generally the case, the invagination had reached the transverse colon, the surgeon could not bring it out of the wound till the part of the large bowel implicated was disinvaginated. This was accomplished by making pressure on the apex of the intussusceptum while the intussuscipiens was pulled in the opposite direction. It was done by grasping the colon close to the apex with the hand, and following it up the bowel step by step till the colon and cæcum were free. The mass was now lifted out of the incision. Then came the most difficult point—the reduction of the invaginated portion of the ileum. The part was grasped in the hand and firmly pressed for a few minutes; then pressure was made with the thumbs on the apex, while the fingers surrounded and supported the outer orifice of the ileo-cæcal valve. The method resembled that used in paraphimosis, only the large bowel covered the part from view. Before the intestines were returned to the abdominal cavity, the contents which had accumulated in the ileum above were forced through the affected part into the colon; this would prove that the difficulty had been effectually overcome and insured an early movement of the bowel. Drainage was not necessary. The omentum was spread over the intestines to prevent adhesion of the bowel to the line of incision. The dressing was covered with oiled silk, the edges of which were sealed with collodion to prevent urine reaching the cut.

Dr. Reed said his experience was restricted to a single case of intussusception in infants. The child was operated upon *in extremis*, and died within the first five hours following operation. With early interference the outcome might have been different.

Dr. Price said the cases reported were a beautiful demonstration of what could be accomplished by good judgment, great diagnostic skill, and early surgical interference.

Dr. W. E. B. Davis thought it was unusual for one man to have so many cases of invagination in infants. He had met with only one case, and this occurred ten days ago, the child, a male, being eight months old.

Dr. Hall recalled half a dozen fatal cases of intestinal obstruction in infants in sixteen years' general practice. He believed the invagination was overlooked in the majority of instances.

Dr. John M. Duff believed that intussusception in infants occurred more frequently than was generally supposed. He had held post-mortems in several cases in which the diagnosis had been doubtful, but intestinal obstruction was found. He had seen two cases within the past year; in one operation was refused, and the

child died. At the autopsy intussusception was found. The other case was operated on after peritonitis had set in, and was also fatal.

Dr. Cumston had seen four cases of invagination in children.

Nursing in Abdominal Surgery.—Dr. Joseph Price, of Philadelphia, read a paper with this caption. The time had passed when any question was raised by intelligent and experienced members of the profession as to the value of the trained nurse. Nurse-training schools had become important institutions, not only to young women who with a creditable ambition entered them to fit themselves for the profession of nurse, but to the physician, for the latter, whether in general or special practice, knew the value of the trained nurse, understood the close and vital relation she held to his patient; how much her care and quick intelligence of needs did to relieve his anxiety and promote the welfare of his patients. The training of these schools should be specially and simply directed to fit pupils for the duties of nurses. These duties in all their details, and all the steps in the training essential to discharge them faithfully and intelligently, should be definitely, orderly, and clearly outlined by teachers of thorough experience. Those desiring to become nurses should commence their work early, while young, studious, and ambitious; while their habits were not so fixed as to make a change difficult, if not impossible. Too much had always been expected of nurses in private nursing. Nursing through twenty-four consecutive hours was too much to require of human endurance, and resulted in neglect of the patient. Systematically trained special nurses were usually bright, cheerful, interested, and spirited: were alive to the importance of their work; cared for and infused into their patient some of their own animation. The untrained nurse, on the other hand, was meddlesome id dangerous. Young, healthy, unmarried women ere to be preferred—not widows, or grass widows, great-aunts, or grandmothers.

Second Day—September 21st.

Dr. W. J. Asdale, of Pittsburg, read a paper in which he reported an interesting case of extra-uterine pregnancy, with a mature fœtus, and exhibited the specimen. The skeletal remains were borne seventeen years over the completion of the gestation term, and the condition was eventually complicated by an ovarian cyst. No operation was performed. The patient died. At the autopsy a monocyst of the right ovary of large size was emptied and withdrawn. One of the long bones of a fœtal skeleton was found free in the pelvis. High in the left hypochondrium, underlying the left lower ribs and just beneath the diaphragm, the remains were found—skeletal—of a fœtal body, disarticulated and closely packed together. The bones were invested by the intestine, a portion of which was cut away in the removal. The fœtal soft parts had, at the time of autopsy, almost entirely disappeared. Records of successful operations undertaken for the removal of long-retained fœtal remains were so rare as yet to be exceptional, and how much more doubtful surely would be the result of operative interference in such a complicated case as this.

Remarks on Primitive Amenorrhœa, with Report of a Case and Presentation of Accompanying Pathological Specimen.—Dr. Walter B. Chase, of Brooklyn, read a paper on this subject, in which he said that the essential fact in the sexual life of woman was the predominating control of ovarian influence, and the central fact in the pathology of woman's sexual life was due in large degree to changes or perversion of function or structure of the ovary. While ovarian function was not the single influence which swayed woman's existence, the absence of it would dethrone her womanhood. The commonly accepted theory concerning the functional activity of woman's sexual life was that menstruation marked the commencement of ovulation, and that in its ordinary manifestations they were, in point of time, coincident. The experience of all observers doubtless furnished exceptions to the common law, but these exceptions served rather to confirm than abrogate it. Among these variations or absence of physiological processes amenorrhœa in some of its forms was of common frequency. An intelligent and comprehensive distinction in amenorrhœa embraced a difference between those cases which were congenital and those which were acquired. In the former, emansio mensium, or primitive amenorrhœa, the causes were congenital, and chiefly physical; while in the latter, suppressio mensium, or acquired amenorrhœa, the causes were functional, or largely so. In the first class menstruation had never been present; in the second class the function once present was arrested. Primitive amenorrhœa might result from congenital deficiency or imperfect development, as follows: absence or imperfect development of ovaries and uterus; degeneration of the ovaries, cystic or otherwise; the formation and development of benign or malignant tumors of the ovaries sufficient to preclude or abolish their function.

Report of Case.—Mrs. B——, aged twenty-four; a woman of refinement and fine physical development; had been married about two years; was sterile, and had never menstruated. She gave an intelligent history of having had all of the symptoms which usually accompanied menstruation, since the age of puberty, except the appearance of the menstrual flow, commencing at about eighteen years. The symptoms of discomfort developed with perfect regularity every twenty-eight days, with a history of increasing pain and nervous excitability, until during the eighteen months previous to his having seen her the pain had become unbearable and nervous perturbation such that she and her friends feared insanity. The one subjective symptom which gave rise to her fears of mental disturbance was severe headache and pressure felt at the vertex, which were present for several days at each menstrual molimen. During a year or more she had been conscious of a gradual enlargement of the abdomen, and could herself easily define an abdominal tumor. She entered the service of Dr. Chase at the Bushwick Hospital, and a careful study was made of her case by the consulting gynæcologist and himself. The patient was desirous of an operation, which was performed. The first tumor removed was a dermoid and had no pedicle, but was closely adherent to the uterus and the right broad ligament. The second tumor was a suppurating multilocular cyst of the left ovary. The report of the pathologist was: (1) The dermoid had usurped the place and destroyed the function of the right ovary. (2) In one of the walls of the multilocular ovarian cyst was found a shrunken ovary, the size of a large lima bean, and within this ovarian stroma was found a corpus luteum spurium. To the presence of this ovarian stroma were due the womanly development, with ovulation, and the futile effort of menstruation and its consequent suffering. (3) It demonstrated the possibility of ovulation without menstruation. (4) It left us in doubt whether the absence of the Fallopian tubes was primary or secondary to the grave disease of the ovaries, with the possibility that they were congenitally absent. (5) It presented the rare and exceptional condition of a perfectly developed woman who had an ovary and a uterus, who ovulated, was sterile, and had never menstruated, and yet was ruined in health by nature's effort to establish an impossible normal function.

The remainder of the morning session was devoted

to the presentation and discussion of pathological specimens. Specimens were exhibited by Drs. John B. Deaver, X. O. Werder, Rufus B. Hall, and William H. Humiston.

President's Address.—This was delivered by Dr. Charles A. L. Reed, of Cincinnati, Ohio. He selected for his subject "The Evolution of Specialism." Modern specialism in medicine, he said, dated from the period when the French schools, in the early decades of this century, took up seriously the question of pathological anatomy. This was the physical basis upon which the work of division began. The obstetrical art was as old as the function of reproduction, although the later ages had witnessed its present refinements. It had been said that obstetrics married surgery, and that the fruit of the union was bright-eyed gynæcology. The accouchement probably occurred at the time Récamier invented the speculum, in 1801. Surgery had its first rational development in the United States in 1809 under the masterly hand of the immortal McDowell; everything from that day to this was essentially contemporaneous history, in which occurred conspicuously many of the proudest American names. Specialism became a verity in response to natural laws, which even to-day determined its destiny. There was not a day but the general medical profession became enriched in resource and potentiality by the accretions derived from specialism. Each specialty, however assiduously cultivated, remained an integral part of the great general profession, the masters of which must ever stand as our ideals. All specialists to-day were primarily the products of general medical culture.

Third Day—September 22d.

Dr. D. Tod Gilliam, of Columbus, Ohio, read a paper on the "Treatment of Granular Erosions of the Cervix," and reported three cases which he had treated successfully by ligation of the cervical vessels.

The Relation of Nervous Affections to Diseases of the Female Pelvic Organs.—Dr. B. Sherwood Dunn, of Boston, followed with a contribution on this subject. He limited his remarks to the great neuroses of neurasthenia and hysteria and insanity. He was totally opposed to any operative procedure, except when pathological conditions were demonstrable. He had no confidence in operations upon healthy organs for the cure of any neurotic condition, and believed that such were now generally condemned by the profession. He, however, looked upon the position taken by some neurologists, that there was no relation of cause and effect between the various neuroses and psychoses and disease of the female pelvic organs, as being as extreme and condemnatory as the advocacy of the removal of normal organs in the female pelvis for the cure of nervous diseases, by some ill-advised persons calling themselves gynæcologists. In operating upon diseased conditions in the pelvis, the gynæcologist did not expect to remove the symptoms of the neuroses, but only those symptoms properly belonging to the pelvic disease itself. But, strange and disappointing as it might seem to be to some of the critics, when those pathological pelvic conditions were removed or corrected, the nervous system, relieved from the source of unceasing irritation, gradually returned to its normal poise, and the patient was cured of her neuroses as well as her pelvic disease.

Graver Forms of Nervous Disturbances Due to Organic Changes in the Genital Organs.—Dr. William H. Humiston, of Cleveland, Ohio, read this paper. In the last five years of his work the essayist had never operated in any case in which the correlation between the diseased pelvic organs and the nervous symptoms was not clearly defined before an opinion from a neurologist relieved him of a doubt of a nerve or brain lesion, with one exception. He reported six cases in which great relief—in some, cure—followed operative interference. The first case was one of insanity; the second, melancholia; the third, neurasthenia; the fourth, insanity; the fifth, hystero-epilepsy; and the sixth, hysteria. The cases were reported with the hope that some effort would be made to secure for women confined in county and State institutions for the insane such surgical measures as would, in a large proportion of cases, be a curative means for their mental ailment, and which must, in a vastly greater proportion, at least improve their condition, both mentally and physically.

Albuminuria Complicating Gynæcological Operations.—Dr. Rufus B. Hall, of Cincinnati, read a paper on this subject. The speaker referred first to the conditions predisposing to this complication. He urged careful examination of the urine preceding operation, so as to determine if possible the presence of nephritis or other causes leading to suppression. The most common cause was a pre-existing nephritis, but unfortunately in granular nephritis a most careful examination of the urine might fail to show the presence of the disease. One of these patients after the operation might have suppression followed by coma and death. The speaker said that we might also have suppression following operation in a patient with a fatty heart or with atheromatous arteries. He considered it of the greatest importance to have the patient thoroughly prepared for operation. If he found the least indication of pre-existing nephritis, he advised chloroform for the anæsthetic, regardless of the age of the patient. In his early operative work he used ether almost exclusively. He cited a hundred and ten sections in which ether was given. In thirty-three cases there was a trace of albumin in the urine in the first twenty-four hours. In ten cases there was partial or complete suppression, and two patients died in coma. During the time he had used the ether, he had operated on seven patients known to have nephritis. They were given chloroform and were included in five hundred sections in which that drug was the anæsthetic. Eighty-five of this number showed a trace of albumin in the urine in the first twenty-four hours after the operation. Ten patients had suppression and four died of uræmic coma. All patients who were known to have kidney disease were given chloroform. There were thirty-five, and the deaths in the chloroform list were from this number. To avoid the dangers from the use of chloroform, the speaker urged that its administration be intrusted only to one expert in its use. He closed the paper with a *résumé* of the preliminary treatment he accorded every patient about to be subjected to a section, of the manner in which he conducted his operations, and of the measures he employed if albuminuria occurred following the operation.

Dr. X. O. Werder, of Pittsburg, gave the clinical observations of over one hundred abdominal sections for ovarian tumors.

Dr. Frederick Blume, of Allegheny, Pa., reported a case of double uterus and vagina with pregnancy in one horn, in which he excised the vaginal septum.

Officers.—The election of officers for the ensuing year resulted as follows: *President*, Edward J. Ill, Newark, N. J.; *First Vice-President*, Edwin Ricketts, Cincinnati, Ohio; *Second Vice-President*, A. B. Miller, Syracuse, N. Y.; *Secretary*, William Warren Potter, Buffalo, N. Y., re-elected; *Treasurer*, X. O. Werder, Pittsburg, re-elected; *Executive Council*, A. Vander Veer, L. S. McMurtry, W. E. B. Davis, John M. Duff, L. H. Dunning, and Walter B. Chase.

Indianapolis, Ind., was selected as the place for holding the next meeting, the time of which was left to the executive council.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 26, 1898.

ARTHUR M. JACOBUS, M.D., PRESIDENT.

Officers Nominated.—*President*, Samuel Oakley Van der Poel and N. E. Brill; *First Vice-President*, Henry C. Coe and Frank H. Daniels; *Second Vice-President*, Charles E. Quimby and J. Clifton Edgar; *Secretary*, William E. Bullard and James H. Burtenshaw; *Assistant Secretary*, John V. D. Young; *Treasurer*, John S. Warren and Henry S. Stearns; *Censors*, Arthur M. Jacobus, Henry Ling Taylor, J. H. Byrne, H. L. Collyer, John T. Nagle, E. B. Bronson, John A. Fordyce, Eugene Fuller, H. T. Hanks, and W. L. Carr.

The Differential Diagnosis by Means of Blood Examination between Tropical and Malarial Fevers and Typhoid Fever, Including their Etiology, Prevention, and Treatment. — DR. JAMES EWING opened the discussion on this subject. He said that his work at Camp Wikoff comprised eight hundred blood examinations in seven hundred and fifty-four cases of suspected malarial fever. In one hundred and twelve cases the æstivo-autumnal organism was found; in thirteen crescents alone were found, and both forms of organisms were observed in five cases. It was no exaggeration to say that at least ninety-nine per cent. of the men at the camp suffered more or less from some form of malarial infection. In the majority of cases at least a week or ten days seemed necessary for the development of the disease. The evidence obtained regarding the relation of infection to the presence of mosquitoes was equivocal, but the soldiers very generally complained of the dreadful exhalations from the Cuban soil. The negroes were much less susceptible to infection than the whites. In most of the cases there was a chill of moderate severity at first, and the fever usually reached its height on the third or fourth day. The impression was very general that the third paroxysm of Cuban malaria proved fatal. The examinations seemed to show that the blood was rarely infected with more than two generations of parasites. The cerebral type was quite common, and unless these cases responded immediately to the subcutaneous administration of quinine death supervened in about twenty-four hours. After one or more acute paroxysms, many cases had a remittent fever. A rather remarkable fact was that not infrequently the anæmia and prostration became steadily worse after the disappearance of the organisms from the blood. In the mild seizures, even when examined at or immediately after the chill, he had been rather frequently unable to find the malarial parasite. Ordinarily, owing to the press of work, it was impossible to devote more than half an hour to the examination, so that it was quite possible that in some instances the parasite would have been found if the search had been more prolonged. The young crescentic forms first appeared on the third or fourth day after the paroxysm. In the febrile period following the acute attack the crescents were usually found in greater or less abundance in the circulation, even in patients who took quinine. He had repeatedly found them two weeks after all distinct acute paroxysms had ceased. Their presence might be the only sign that an apparently cured case was liable at any time to be followed by a relapse. The majority of the comatose cases, seen in the camp, came from the regimental camp. In most of these cases the crescents were found in abundance, but occasionally they were not observed until a careful and prolonged search had been made. The coma was apparently referable to some embolic process, and not to the discharge of spores. Sporulation seemed to be invariably followed by rise of temperature and increase of the pulse rate. In a considerable number of mild paroxysms with slight rise of temperature and associated with restlessness or vomiting, young crescents were found in considerable number, leading to the conclusion that the presence of these organisms was responsible for the occurrence of many of the acute phenomena of malaria.

Malarial Remittent.—In many of the acute remittent cases isolated crescents were found, but in a larger proportion no distinct organisms were found at all. In these cases, however, pigmented leucocytes were found, and this was so uniform that Dr. Ewing expressed the opinion that the presence of these leucocytes constituted the most characteristic feature of ordinary malarial remittent fever. When associated with marked anæmia, the diagnosis was almost certain.

Mixed Infection: Typhoid Fever and Malaria.—A great many cases which were indistinguishable from typhoid fever without the most careful clinical examination proved to be clear cases of infection with the æstivo-autumnal organism of malaria. Over two hundred cases of typhoid fever were studied, and in nearly all of these there was also malarial infection. In spite of these favorable conditions for mixed infection, in no undoubted fatal cases of typhoid fever (in which the diagnosis was confirmed by autopsy) was the malarial organism found. In five cases of typhoid fever the plasmodium of malaria was found in the blood during acute exacerbations occurring during convalescence from the typhoid fever. From these observations the following conclusions were drawn: (1) Mixed infection of typhoid fever and malaria undoubtedly exists. (2) When typhoid develops in a case of active malaria, the malarial element nearly always becomes quiescent, and has little or no effect on the course of the typhoid fever. (3) Malarial infection frequently outlasts the typhoid infection, and makes itself manifest during convalescence.

Pernicious Malaria and Amœbic Dysentery.—In nine cases of pernicious anæmia and amœbic dysentery, the æstivo-autumnal organism was found in the blood and the amœbæ were present in the stools.

Widal's Test.—Dr. Ewing said that his experience at the Montauk camp with Widal's reaction had been unsatisfactory, probably owing to the very unfavorable conditions under which it was necessary to conduct the bacteriological work. It was possible that the very large doses of quinine, by subcutaneous injection, had some influence on the Widal reaction. A very striking group of cases was that in which severe vomiting in afebrile cases was associated with the presence of the malarial organisms in the blood. The value of blood analysis in cases of tropical fevers had been abundantly demonstrated at this camp. Some of these fevers, that had been proved by such examination not to be malarial, seemed to improve more rapidly after the withdrawal of the quinine.

DR. W. GILMAN THOMPSON continued the discussion by a report of his experience with these cases after they had reached the Presbyterian and Bellevue hospitals. He had studied one hundred and seventy-three cases. Some of the cases came from Santiago, others from Porto Rico, and others from Chickamauga. Typhoid fever not being endemic in Porto Rico, the cases coming from there were probably of American typhoid, which had been carried there and brought back again, so that they came under observation rather late in the disease.

Special Clinical Features.—In many of the cases there had been great difficulty in making the diagnosis at first. Many of the patients suffering from the æstivo-autumnal variety came under observation at a time when the fever had been more or less continuous, and the symptoms resembled more closely those of typhoid

fever. Usually the malarial spleen was larger than the typhoidal spleen, but in the cases under consideration this had often been reversed. In bad cases of malarial infection there was often seen the mental hebetude so generally observed in typhoid. The temperature had very generally been lower than that observed in our ordinary cases of malaria here. Icterus, anæmia, and herpes were found in these cases of typhoid fever, as well as in the cases of malaria.

The Serum Test.—The serum test for typhoid fever had been applied in all of the cases. It was now known that the serum reaction had been observed long after a genuine attack of typhoid fever—even from three to ten years afterward. Although, therefore, its negative value was not great, it had a distinct and positive value as a confirmatory test. In a series of four thousand reported cases of undoubted typhoid fever, the reaction was present in ninety-five per cent. He had himself collected a number of cases, apparently accurately observed, in which this serum reaction had been noted in other diseases than typhoid fever. It was very unfortunate that among these diseases were those which were most apt to be confounded with typhoid fever—for example, malaria. The test was of little or no value before the seventh day of the disease, and quite frequently it was not obtained until considerably later—indeed, in quite a number of cases it was not observed until the relapse.

The Plasmodium May be Found during the Course of Typhoid.—Regarding mixed infection with typhoid fever and malaria, the speaker said that four or five years ago he had reported several cases in which clinically there seemed no doubt as to the diagnosis of typhoid fever, and yet the malarial plasmodium was found in the blood during the course of the disease. At the time of these observations the Widal reaction was not in use. Since this time several other clinical observers had made similar reports.

Dr. C. E. Nammack then presented the results of his study of these cases in the fourth division of Bellevue Hospital (see page 471).

Limitations of the Widal Test.—Dr. William H. Park said that he had had a rather large experience with the Widal reaction. Only to-day the health department had received forty-seven specimens for examination. His own experience with the test was that the rapid clumping with a 1 to 10 or possibly a 1 to 20 mixture was obtained only with typhoid fever. The reaction was not quite so rapid with the latter dilution. To avoid confusion he thought it very desirable that the line should be quite sharply drawn here. This intense reaction was not obtained early in many typhoids, and not at all in many others; hence the test should not be considered as having any negative value. While it was true that the reaction was occasionally observed long after an attack of typhoid fever, it was rarely observed after the expiration of six months.

Mixed Infection.—Regarding mixed infection, Dr. Park said that he had inquired as to the experience of the various hospitals in this city, and in all but one hospital the malarial organisms had been found in the blood of from one to five per cent. of the typhoid-fever cases.

Dr. Alfred Meyer said that there had been thirty or forty of the soldiers at Mount Sinai Hospital this summer, and he had made an effort to collect evidence of simultaneous infection with typhoid fever and malaria. In only one instance was there any approach to such infection. Unfortunately this man came to the hospital too late to show anything more than the existence of malarial poisoning during convalescence from typhoid fever. The Widal tests at this hospital had been carried out with a dilution of one part of blood to twenty parts of distilled water or of the serum, and every effort had been made to conduct these observations with scientific accuracy.

Typhoid Fever at Camp Black.—Dr. N. S. Jarvis said that he had been stationed in this city, and had consequently had the cases under his observation only for a short time. But on a visit to Camp Black he had seen one hundred and sixty cases of typhoid fever, and had endeavored, with the medical officer there, to determine the origin of the disease. At that time there was no typhoid fever in Hempstead. It was evident that the old pits had not been thoroughly covered up, and some of the kitchens were situated near these pits. His own opinion was that the typhoid fever originated at this camp, either at these points or from the wells in the neighborhood. One of the springs most frequented by the soldiers was within twenty-five feet of a privy.

Treatment of Cuban Malarial Fever.—Dr. A. M. Lessèr said that the typhoid-fever cases that he had seen in Cuba were at Siboney, and were observed very shortly after the arrival of the American troops. The patients all had a rather typical temperature, and recovered without complications. Dr. Lessèr then read a report regarding the cases on the *Concho* and the nature of the fevers. He stated that when the soldiers were taken on this ship they were apparently well. There were on board some typical cases of both intermittent and typhoid fever, together with some other Cuban fevers. In these fever cases there was often an initial rise of temperature to 106° or 107° F., with a pulse of 130, and without a corresponding acceleration of the respiration. This fever lasted, with but few remissions, for thirty or forty hours. Then the temperature began to fall, and quickly reached 101° or 102° F. In the evening it rose again, but fell during the next night, and the patient had a profuse sweat. After this, some went on uninterruptedly to convalescence, while others had remissions and exacerbations for an indefinite time. Such fevers were especially observed on the ship among those who were convalescent from yellow fever. The anæmia was very marked. The malarial plasmodium was uniformly found in the blood on the fourth day in spite of the large doses of quinine. This organism still persisted in the blood when the patients appeared to have recovered. His treatment had consisted in an initial dose of a saline cathartic. It was found that the intense headache was best relieved by small doses of gelsemium. Finding that the large doses of quinine had but little effect while the temperature remained high, smaller doses were given at intervals of a few hours, along with hydrochloric acid. No food, either solid or liquid, was given while the temperature was above 101° F. After recovery from the acute attack great care should be taken properly to restrict the diet, and convalescence would be assisted by the administration of a tonic consisting of sulphur, camphor, and capsicum. The malarial plasmodium disappeared from the blood much more quickly under the use of this tonic than under the administration of quinine. Of the forty-one hundred and sixty-two cases of sickness under his observation, twenty-four hundred and twelve were of Cuban malarial fever, and all ended in recovery.

Conditions at Camp Alger.—Dr. Elmer Lee spoke of his experience at Camp Alger. He said that if one-half of the money spent for medicines and such unimportant things as proprietary articles and flannel bandages for the abdomen had been applied to the purchase of proper accommodations for bathing and promoting personal cleanliness among the troops, there would have been much less sickness. His own experience was that the number of nurses at the camp was sufficient, but the work would have been better done by women. The methods of cooking and serving

the food were unnecessarily primitive. The number of cases of fever at this camp was not excessive, considering the conditions under which twenty thousand volunteers were brought together. From two to ten per cent. were sick, and many cases of illness were due to overloading the stomach with food and not taking sufficient water. Many of the men abstained from drinking, fearing that the water was not good, whereas as a matter of fact it was as good at this camp as in New York City. Too little thought was given also to properly clothing the soldiers.

Conditions at Mobile and Miami.—Maj. Daniel Mitchell Appell, surgeon, U. S. A., said that he had been at the camp at Mobile last spring. There were six regiments of regular infantry and two of cavalry. Most of the regiments remained there for four or five weeks, and during this time there was very little sickness. The camp was supplied with water from the water supply of Mobile. The Texas troops had been mustered in at their State camp, and they had cases of typhoid fever among them before reaching the Mobile camp. The same was true of the Louisiana regiments. The Alabama troops were encamped on the bay shore at a notoriously unhealthy spot, and in spite of the protests of the medical officers of the army and of the city. They brought in a number of diseases, including small-pox. Out of eleven hundred men, two hundred were sick shortly after their arrival. The division moved to Miami, Fla., about July 1st. Here the climate was very similar to that of Cuba. The sickness rapidly increased here, so that at one time nearly fifteen per cent. of the command were sick. Most of the cases, however, were instances of mild malarial infection. Typhoid fever had been unknown at Miami for years previously. No preparation had been made for the camp, and it became necessary to clear the ground for that purpose, which during this season of the year was contrary to the State law. There was a great deal of malaria here, and all of the men seemed to become quickly enervated. They were improperly clothed, and were compelled to do a great deal of drilling. The water at this camp was taken from a stream which ran from the Everglades—a large morass. This water tasted and smelled swampy, though analyses showed that the water was potable at the time of the arrival of the troops. Before the water could be piped to the camp a number of pumps were used temporarily, and undoubtedly many of them became sources of infection. Sewers were also constructed, but the work was done by inexperienced volunteers and consequently it took much longer than it should have done.

Dr. Ewing, in closing the discussion, said that it might appear to many that he had emphasized too strongly the importance of the pathological evidence of mixed infection of malaria and typhoid fever, but it was just because of the doubts and uncertainties which surrounded this subject that he had brought forward so prominently his positive, though comparatively limited, experience. To his mind, the value of anatomical evidence was greater than clinical evidence as to the nature of these mixed infections.

Memorial to O'Dwyer.—Dr. T. J. McGillicuddy presented a resolution, which was adopted, calling for the appointment of a committee of three, whose duty it should be to take steps looking toward the raising of the necessary funds for a suitable memorial to Dr. Joseph O'Dwyer. The committee consists of Drs. McGillicuddy, A. Jacobi, and Louis Fischer.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HOT SEASON—THE WATER FAMINE—THE COMING SESSION — POST-GRADUATES — ANOTHER POST-GRADUATE SCHEME — NURSING-HOME SCANDAL — BELFAST EPIDEMIC—BRITISH ASSOCIATION — PRESIDENT'S ADDRESS—PREDICTS A WHEAT FAMINE.

London, September 9, 1898.

The heat wave soon passed by, but left fine warm weather behind. We have, in fact, had the warmest August since 1893. But, though we talk so much of heat, you would think little of it, judging by the figures reported from your side in our newspapers. Indeed, the thermometer reached only 89° F. on August 21st, and, though the month has been a warm one, the temperature has been only slightly above the average. Much the same may be said as to June and July. The periods of sunshine recorded at the meteorological office show, further, that we have had no excess. In June the number of hours of bright sunshine was 127, against an average of 167. In July there was a gain, and we had 163, one above the average. August made up for it by giving 189, against an average of 151.

Thunderstorms have been rare, and, what is more important, the rainfall has been below the average.

But all these figures do not justify the pretence of the East London Water Company, that prolonged drought is the only cause of its failure to carry out its contract. One fact shows this, viz., that the other companies have experienced no difficulties and can even afford to sell to the defaulting company. A further excuse has been that there is undue waste in the district, and the local government board seems to have accepted this statement, for it has addressed the vestries on this alleged "large waste, in some cases wilful, in others the result of carelessness." The Hackney vestry has sent a spirited reply to this "charge," and declares it to be "without a shred of evidence in its favor." This vestry has come to the rescue of the poor with water carts in parts where the company has no pipes, and has done good service. Its committee protests indignantly against the "gross libel," and expresses "astonishment that the government board should have made such an accusation on an *ex parte* statement of the authority which is solely to blame for the scarcity of water."

The Shoreditch vestry has replied in still more forcible terms and with a dash of sarcasm, which may well make the clerks of the board rub their eyes, and even "my lords," in whose names they write, wake up to the necessity of action directed by reason.

The probability is that this charge of waste of water by the victims of its scarcity only covers a leakage from the company's mains.

There are signs of the approach of the new session at the medical schools. Teachers who have returned from their holidays are talking of the 1st of October and speculating on the probable entries. The arrangements for opening the session are well advanced. *Conversazioni* and dinners maintain their encroachments on the time-honored introductory lectures, but these latter will also be represented. The *pièce de resistance* undoubtedly is offered by Charing Cross Hospital, for this school has secured the promise of an address by Virchow, who cannot fail to draw. The veteran pathologist will be duly dined and feted.

Another sign of approaching October is the appearance of the students' number of each of the medical journals. This annual number is for the most part made up of reprints of official regulations and prospec-

tuses. It is supposed to be consulted by parents in selecting a school, but I doubt if this is often the case. There is usually a leader of advice to students, but even that is probably neglected for the advice of the teachers at the school which has been chosen.

What will probably be of greater interest to your readers is the facility of post-graduate instruction in London. Not so long ago clinical instruction for qualified men was without organization. Visitors were welcomed for a time to see the practice, and had only to bring an introduction or present a card. Of late years there has been an effort to follow in the wake of New York. Classes for graduates have been arranged at several institutions, and vacation courses have also been given.

Now another arrangement has been made, which will prove a formidable competitor to the post-graduate courses. This is no less than a sort of union between all the hospitals having schools attached (except the London and St. Bartholomew's). This union will issue tickets admitting to the clinical instruction of any or all of the nine hospitals included, at a single fee of 7 guineas for three months, or 10 guineas for six months. It is anticipated that qualified men will avail themselves of this opportunity of seeing the practice of various teachers, that visitors from a distance will be glad to obtain for so moderate an outlay entrance to some of the hospitals in an independent manner, and that the scheme will react favorably on the schools and on the teachers.

Nurses we have always with us, and sometimes their vagaries are very trying. The spread of nursing-homes, too, is not altogether a blessing to the profession. They are too often abused. Some of them are rather homes for unqualified practice. Lately the profession in an Eastern suburb has been obliged to combine against the action of a local maternity charity, which sent out its nurses to attend midwifery cases at a fee of 5*s*. To a protest on the part of the doctors the "charity" has calmly replied that it will raise the fee of nurses' attendance to 10*s*, except when the husband's wage is £1 a week or under, and, further, except for patients furnished with a recommendation from a clergyman or medical man. It is easy to see that such a plan is liable to gross abuse. It appears that the "charity" is ready to undersell the profession in all ways, and purposes to extend its operations among the more well-to-do further than it has hitherto done. Of course, if it continues to obtain subscriptions it can easily do this. Here we have a sample of numerous cases in which so-called charities existing on subscriptions are ready to snatch the bread from the mouths of the most ill-paid members of the profession.

This maternity home has lately been before the coroner for the district in reference to the death of a child, and it looks almost as if the charity was carrying on something in the nature of a baby farm.

The typhoid epidemic at Belfast seems to be abating. The number of fresh cases notified during the week ending on Monday night was 269, as against 333 in the previous week, and the decrease has been fairly steady from day to day. Of course this may, as is hoped, go on, but a recrudescence is always to be feared, and Belfast offers a sad instance of prolonged sanitary neglect.

The annual meeting of the British Association for the Advancement of Science opened at Bristol on Wednesday, under the presidency of Sir William Crookes. The Colston Hall, the largest suitable building in Bristol, was last week burned down, to the consternation of the local committee as well as of the city. Every effort was, however, put forward to meet the emergency, and the meetings are proceeding.

The president succeeded in his address in keeping up the custom of making a startling statement, which has prevailed for a few years. Of course he passed in review the more recent discoveries, but more than half his time was devoted to a discussion of the great problem of providing food. He calculated that if the present rate of increase in population is to go on, the world will be unable to provide a wheat-growing area to supply the bread required by the year 1931. What then? Is the Caucasian race to be squeezed out by those who do not eat wheaten bread?

Sir William Crookes does not say this, but, after rebuking us for throwing nitrogen away in sewage to the tune of £16,000,000 a year, says we must look to chemistry for a supply of that element. The free nitrogen of the atmosphere is the source to look to—as all others will be exhausted—and that can be fixed by electricity generated by water power. Here is hope for the Caucasians, for he reckoned that Niagara could be thus made to yield sodium nitrate at £5 per ton or less, while Chile nitrate costs half as much again—and the great cataract could supply the energy required without much lessening its mighty flow.

HEART DISEASE AND TALL SCHOOL-HOUSES.

To the Editor of the Medical Record.

Sir: A matter which has been most forcibly brought to my attention, on account of chronic heart trouble of one of my own little ones, is the unusual height to which the public schools of this city are being built.

In this particular case the little one was utterly unable to climb the five flights of stairs required to reach her classroom. After several days' attendance, at the beginning of the school session, her trouble became so marked as to require her remaining away from school until such time as rest would correct the injury brought on by the unusual exertion to which she had been subjected.

In another case, dating back a few years, the daughter of a colleague had recently recovered from scarlatinal rheumatism, followed by marked heart lesion; after she had made several efforts at regular attendance during a period of six months, it was found absolutely necessary to withdraw this child from the public school and have her education continued in a schoolhouse which did not require such high stair climbing.

In the two cases just mentioned no serious deprivation of education would occur to either child, as it is possible for the parents to avail themselves of other means of instruction than those obtained in the public schools; but in many cases, when children have recently recovered from any disease which weakens the heart, the strain required by high stair climbing to reach classrooms would still further weaken it, and probably to such an extent as to require their removal from these schools and so deprive them of an opportunity to receive a liberal education, on account of lack of means on the part of the parents to send them to other schools where such conditions would not exist.

As the city of New York is spending money without stint for purposes of educating the coming generation, erecting public school buildings replete with every sanitary arrangement to prevent the communication of disease, and architecturally, in almost every case, ornaments which the citizens may well be proud of, I think that some of the more ornamental features might well be dispensed with, and the money so saved used for the purpose of installing one or more elevators for such children as those mentioned above and who present certificates from their physicians to the principal of the school of their inability to climb several flights of stairs; or a larger space of ground could be taken and lower buildings erected, the classrooms of which

could be reached without difficulty oy any child whose heart was more or less seriously affected, and also be more readily emptied in case of fire.

MICHAEL B. FEENEY, M.D.,
Chief Sanitary Inspector.

32 EAST THIRD STREET, September 26th.

THE QUALIFICATIONS, RESPONSIBILITIES, AND DUTIES OF THE REGULAR ARMY SURGEON—A REPLY TO DR. SENN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of *The Journal of the American Medical Association* for September 3, 1898, there appears an article by Dr. Nicholas Senn on "The Qualifications and Duties of the Military Surgeon," the object of which appears to be an attempt to demonstrate the inferiority of the personnel of the present medical corps of the army to physicians in civil life, particularly those at present in the volunteer service. The author is a man of such wide reputation and acknowledged distinction in his specialty of practice that, it seems to me, his specious argument and unjust conclusions should not go unanswered. Although those whose names and position would make their evidence of weight and value in the refutation of these charges do not seem inclined to defend the corps against them, as one of the younger members of the medical corps I feel constrained to take issue with Dr. Senn and to deny the justice or correctness of his conclusions. Notwithstanding the contrast between my own position as one of the junior army medical officers and the eminence of the surgical specialist who has produced this article, I am tempted to break a lance with him, taking courage from the knowledge that—

> "Thrice is he armed who hath his quarrel just,
> And he but naked, though locked up in steel,
> Whose conscience with injustice is corrupted."

Dr. Senn speaks of the "lethargy" and the "ease and luxury" of the senior members of the corps; of their use of "compends" in preparing for examination, and, as to the corps in general, of its inferiority in the "practical knowledge required in the treatment of injuries and disease." These are quite serious charges, it seems to me, coming, as they do, from such a source.

Any one who has been connected with the army in time of peace will know at once that these statements are incorrect, but others might not unnaturally be expected to believe them. The life of the army surgeon is a hard one at best; any one who will take the trouble to examine the papers required in the examinations for the grades of lieutenant, captain, and major will see that they cannot be passed by the use of "compends;" and the annual reports of the surgeon-general will show that the results attained by army surgeons "in the treatment of injuries and disease" are unsurpassed anywhere. The members of the army medical corps are graduates of the foremost medical colleges and hospitals of this country, are selected after a most severe competitive examination including laboratory and clinical subjects, and are obliged to "familiarize themselves with the most recent advances in medicine and surgery," if they retain their commissions. So far as my observation extends, the average national guard surgeon belongs, on the other hand, too often to the type of practitioner who, illiterate at the start (as admitted by Dr. Senn), graduates at one of the inferior medical colleges, subsequently accepts the Woodbridge method of treating typhoid fever as a great therapeutic discovery, and seldom prescribes an official preparation when he can find a proprietary article in the drug store. Laboratory methods are a sealed book to him, and I do not believe there are half a dozen men in the volunteer medical service who could make a sanitary analysis of a water sample. I wish to present here a few specific allegations against the national guard surgeons (as exemplified by their greatest representative and most distinguished mouthpiece), which I think will leave a doubt in the mind of any unprejudiced reader as to their superiority to the regular army surgeon.

1. In the article quoted, Dr. Senn says (and I believe him entirely correct in this statement) that "the first and most important duty of the military surgeon during active warfare is to prevent disease and unnecessary suffering by giving early advice and resorting to timely precautions. The location of camps, policing of the same, the water supply, food, and clothing are subjects which must receive his early and earnest attention." How many national guard surgeons have any experience in this direction? In the issue of *The Journal of the American Medical Association* for July 2, 1898, p. 35, Dr. Senn says: "The water is wholesome and palatable. . . . The only microbe which I was able to cultivate was the colon bacillus, and the presence of this microbe could be readily accounted for by the blocking of the sewer pipe, an evil which was promptly remedied." Now I do not believe that any officer in the army medical corps would make such a statement as this in reference to a water supply; the whole article would lead a professional sanitarian "to suspicion" that the perusal of a "compend" on hygiene would do no harm to the author in the event of his taking part in another war.

2. Dr. Senn's article is unprofessional and unethical, particularly, coming as it does from a member and ex-president of the American Medical Association. I think it is a violation of the spirit if not of the letter of the code of that association. If his criticisms were just, the fault would lie in the system rather than with individual officers, and the author has brought them forward at a very inopportune time for the interests of the present junior members of the army medical service. As is known to every one, the worst type of sensational journalism has selected the doctors of the war with Spain as scapegoats for the inevitable misfortunes of war, and it can be readily seen that the professional army surgeon is the only one who has anything permanently at stake and must bear the burden of any opprobrium that may result. Medical men all know what investigations of professional subjects by the laity are likely to amount to, no matter how high the personnel of the investigators. They might consider it advisable to inject a little new blood (of the vigorous volunteer variety) into the higher ranks of the medical corps in order to arouse it from its "lethargy." It is needless to point out that such a course as this, if allowed by Congress, would result in the complete ruin of the professional prospects of junior medical officers.

3. No regular army surgeon would speak or publish the statement that it was "the arrogance or stupidity of the commanding general of the invading army that is responsible for the extensive outbreak of yellow fever during the Cuban campaign." If he did, he would violate paragraph 4 of Army Regulations and probably be promptly court-martialed under the twentieth article of war. He would not desire to do so in any event, for he has learned the first principles of army discipline. The volunteer spirit of insubordination and lack of discipline (fostered by the newspapers and the women) have led to many evils in the present war, such as the making of perfect babies out of men who are supposed to be soldiers, and an utter subversion of discipline which, on account of association, it may take even the regular army a long time to recover from. Any one who intelligently reads the daily press will understand the point I am making,

especially if he has ever done any active service in time of war.

I believe that the whole trouble with Dr. Senn lies in the fact that his *ipse dixit* has been accepted so long in all matters pertaining to operative surgery he is inclined to believe he can speak *ex cathedra* about another distinct speciality—army medical administration—which he has temporarily invaded. This, coupled with his well-known *cacoethes scribendi*, will sufficiently explain his remarkable article.

There is, unfortunately, a hysterical idea prevalent among the laity, and I fear among some professional men as well, that the one thing needed in the medical line in time of war is brilliant operative dexterity. As a matter of fact, operative work is a matter of secondary importance in army medical affairs. All doctors can operate with reasonably good results, especially since the introduction of antisepsis and the modern small-calibre firearm, but none without army experience can organize and successfully administer large military hospitals. Then the records of all wars show much greater incidence of, and fatality from, internal diseases than from wounds and their results. Another very important point is the training of the army surgeon in theoretical and practical hygiene, particularly military sanitation. This the civil practitioner does not study and, naturally enough, cannot learn in a short campaign.

In conclusion, I desire to express my regret at being drawn into anything resembling a newspaper controversy. This is my first and probably last essay in that field. I simply felt that my corps should be defended from the aspersions cast against it by such an eminent man. I am sorry that one of greater prominence, one wielding a more facile pen, has not done something in its behalf. I have always had the greatest admiration for the professional and scientific ability of the author of the article reviewed. His work in introducing the knowledge of modern surgical pathology into this country (not to speak of his great skill as an operator) would alone entitle him to recognition as one of the greatest medical men this country has produced. I trust that, in the future, he will confine his genius to those fields in which it is so well qualified to range. Very respectfully,

CHAMPE CARTER MCCULLOCH,
Captain and Assistant Surgeon, U. S. A.

WEST TAMPA FIELD HOSPITAL, TAMPA, FLA.,
September 18, 1898.

HAS A GREAT OPPORTUNITY BEEN LOST?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your esteemed paper of last Saturday (September 17th) recorded, under "News of the Week," the magnificent gift of $1,500,000 for a Cornell Medical College, from Mr. Oliver H. Payne. This means another medical college added to the many already existing. When, a year ago, the medical press announced the prospective union of Bellevue and the University medical colleges, all true lovers of advanced medical education in our country rejoiced, for this would have created one greater and better-equipped school, instead of two rival institutions. But a controversy arose, the facts of which are too well known to need repeating. Enough that it resulted in a split, and, although the two colleges finally united in name, their respective faculties, both composed of equally prominent members of the profession, separated, and a new medical college (a rival to the University Bellevue Hospital Medical College) sprang into existence.

Paris, Berlin, and Vienna, the greatest centres of medical learning in the world, each have but one medical faculty. Why must New York have a dozen (this is the actual number of chartered medical colleges now existing in the city of New York)?

Is it a wonder that even our best medical schools do not receive abroad the prestige which they deserve? It is the multiplicity of medical schools in the United States which weakens their standing.

Never in the history of medicine has there been presented from one individual in the interest of medical education so munificent a gift as the one above referred to. What a great school would have been the result of the actual union of the two faculties with men like Mr. Payne as trustees! The combined facilities for clinical, experimental, and didactic teaching, which the new Bellevue University College and the new Cornell school would offer, could hardly be surpassed by any school in this country or abroad. These two schools combined, and perhaps a future amalgamation with the excellent medical department of Columbia University, would make Greater New York the possessor of the best, the largest, and the richest medical school of the old and new worlds.

Perhaps it is not too late yet, and all lovers of advanced medical education in this country may yet see realized this beautiful dream of one great medical faculty in Greater New York.

The medical press has been largely instrumental in obtaining the higher standing which our medical colleges now enjoy, and has recently advocated the amalgamation of medical schools and the reduction of their number.

Let the good work go on, and let us hope that the grand opportunity for uniting the two great faculties is not yet lost. S. A. KNOPF, M.D.

955 MADISON AVENUE.

ONE OF THE CAUSES OF AN EPIDEMIC OF TYPHOID FEVER IN MILITARY CAMPS. SPECIAL REFERENCE TO CAMP CUBA LIBRE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: When there is an epidemic or many cases of typhoid fever occur at any place, the first thought is of the water supply. The water used by all the soldiers encamped at Jacksonville, Fla., is from artesian wells, eight hundred to a thousand feet deep, and piped to each company. There is no way by which it can become contaminated. When the first regiment of troops arrived at the camp, they found this artesian water awaiting them. And it has preceded the other regiments.

Three days after the first regiment arrived, a surgeon stated that three soldiers had typhoid fever. Other regiments brought it with them. The second Mississippi brought six or eight cases.

The regiments encamped within the city limits immediately built privies, which had tubs to hold the fæcal discharges, and these were hauled away at night. Other regiments as they came, and these first after they moved camp, dug sinks for the excreta. The contents of the sinks were supposed to be covered over with earth once or twice a day, at first.

The company kitchens were only a short distance from the sinks and privies. Many of the regiments had canteens, where various articles of food, etc., also beer and other drinks, were sold. Around the different camps there sprang up almost as if by magic many small houses in which were sold soft drinks, melons, fruit, cakes and pies, and other things. Each of the latter places, of course, had to be supplied with a sink, which could be used by soldiers if they desired.

Flies encamped with the soldiers, and increased by the thousands. They swarmed over and upon the ex-

creta in the tubs and sinks. When interrupted, some would, with feet, legs, proboscides, and perhaps wings and body carrying typhoid germs, seek new pastures round the company kitchens, the tables of the restaurants, the counters of the canteens and the booths. These places were never lacking of them. They were on the glasses, cups, plates—everything, and, of course, the food. What easier or more certain method could there be of spreading the typhoid bacilli? In my humble judgment there is no other possible way, at this camp, by which so many soldiers could contract typhoid fever. If this is true, or if it is even one of the principal ways the disease has spread through the camp here, then it can also be the principal method of its extension in the other camps. I have been informed that flies were very numerous in all.

Private soldiers in camp usually act as big, overgrown boys, and need the intelligent, watchful, and kindly care of the officers. The government furnishes abundant food, of the best quality and sufficient variety. The officers should not only see that the men get it, but also that it is properly cooked and served in the most cleanly manner possible, thus preventing much sickness. The officers certainly should be as sedulous in seeing that the best sanitary regulations are carried out, as they usually are in pressing the drill and manual of arms. The one is as important as the other. And when it is correctly done there will no longer be the reproach that in war twice as many soldiers die of disease as are killed and die from wounds. The sinks should have strict attention given them. The fæces should be covered with earth immediately by each soldier. Besides, proper disinfectants should be freely used.

Where camps of instruction are established, as at Chickamauga, Camp Alger, Jacksonville, etc., it would be economy to have the company kitchens screened to exclude flies, as some of the officers' kitchens or mess tents have been here. The cost would be a mere bagatelle compared with the amount paid for pensions on account of deaths from diseases that might be thus prevented.

Very few of us in this country will believe that selected, healthy volunteers cannot be congregated in properly located camps, in the South or the North, without their ranks being thinned by preventable diseases.

I have just read, in to-day's *Times-Union*, a statement by Dr. James Carroll, bacteriologist of the National Medical Museum in Washington, who was sent here by the war department to investigate the diseases prevailing among the soldiers at Camp Cuba Libre, that there is not a single case of malarial fever in either of the seventh corps hospitals—that all the fever is typhoid. This certainly speaks well for Jacksonville, for the typhoid was brought here by the soldiers.

E. M. Nolan, M.D.

Jacksonville, Fla., September 18, 1898.

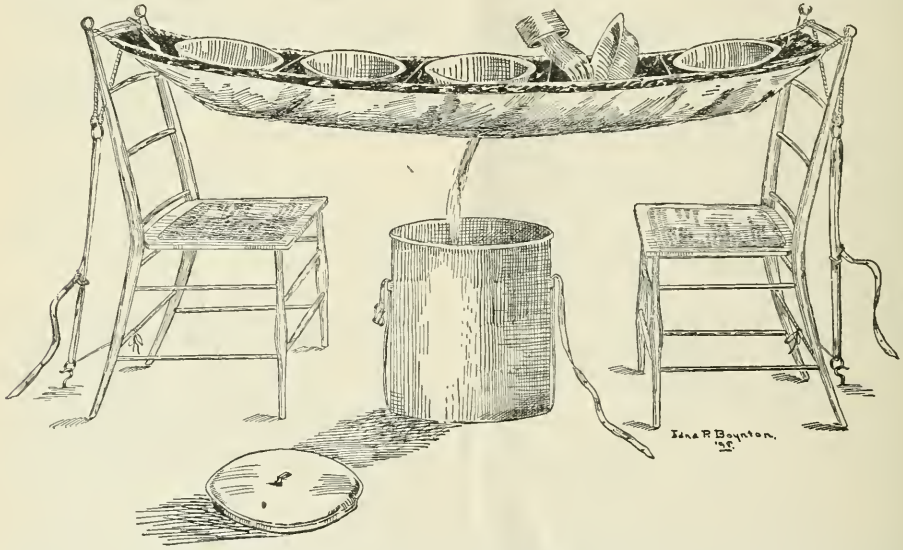
New Instruments.

THE HAMMOCK WASHSTAND.

By CEPHAS L. BARD, M.D.,
VENTURA, CAL.

The utilization of chairs or tables as washstands during operations performed in homes, necessitating, as it does, frequent handling of the basins in emptying and filling them, is unconformable to the requirements of aseptic surgery. That the danger of infection is greatly enhanced by this practice is indisputable.

To reinforce this weak link of the chain of surgical technique, and to provide the surgeon with a convenient and economical device, I would call his attention to "the hammock washstand" invented lately by myself, and which he can readily procure, no matter how remote he may be from the depots of surgical supplies.



By reference to the illustration it will be seen that it consists of a hammock composed of rubber cloth, canvas, or other suitable material, five and one-half feet in length and fifteen inches in width. Its simple construction and position are well shown in the illustration. It is stretched over the backs of two chairs, and its lateral supporting cords are drawn taut by a strap and buckle connecting each end with screw hooks placed in the floor. Additional rigidity is attained by lashing the lower rungs of the chairs to the hooks. The rims of the basins, preferably of granite iron ware, and five in number, rest upon the lateral supporting cords, which are maintained in their proper relation by stay-cords, four in number, which are clearly shown in the cut. It will be observed that, while the width of the material used in the construction of the

hammock proper is fifteen inches, the distance between the lateral supporting cords is somewhat less than the diameter of the basins.

When placed in position every basin is easily tilted and emptied by the immersed hand of the operator, as shown in the illustration, and the withdrawal of the hand is instantly followed by the return of the basin to its original position, owing to the rotatory or pivotal action of its rim on the edge of the hammock. The expelled contents of the basin pass through a circular opening, one inch in diameter, in the hammock's most dependent portion, into a pail, made of galvanized iron, tin, or other suitable material, placed beneath it, and which serves also as a receptacle for the storage and transportation of both hammock and basins. Before being placed in position the hammock and basins are thoroughly sterilized by being boiled in their container on the kitchen stove. Scrub brushes, trays for instruments, and other articles can be carried and sterilized in this same pail.

If the handles of the pitchers used in replenishing the empty basins be covered with sterilized gauze, the danger from infection by contact will, so far as this feature in technique is concerned, be reduced to a minimum. As will be readily understood, the features of this device can be utilized in making a permanent washstand in the operating-room of the hospitals, substituting a metallic trough for the hammock and a waste pipe for the pail.

Therapeutic Hints.

Treatment of Cirrhosis of the Liver.—Dr. J. Barr, after excluding the rarer etiological possibilities, recommends that alcohol be interdicted and the gastritis treated; and further, that a large sinapism be applied over the epigastrium and liver. If there is portal obstruction he advises restriction of the fluid ingested, as the work of the heart is thus lessened. To relieve the hepatic and portal engorgement he employs calomel; but he objects to hydragogue cathartics for the purpose of reducing ascites. Digitalis and a little nitroglycerin may be used as diuretics to diminish peripheral resistance; he has found copaiba useless. If paracentesis be necessary, it should be done early, before the abdominal walls are relaxed. If the walls become relaxed, tapping is accompanied by distressing meteorism. In certain cases venesection and the establishment of a collateral circulation may be used.—*St. Louis Medical and Surgical Journal.*

Treatment of Palpitation.—Dr. Henri Huchard treats this symptom according to its cause. The palpitation of toxic origin (coffee, tobacco) or from drugs (quinine) disappears when the cause is removed. If it is of gastro-intestinal origin and generally nocturnal, due to dyspepsia, with excess of hydrochloric acid, alkalies in sufficient dose and regulation of diet are necessary. Iron does not produce palpitation unless in consequence of its intemperate administration, as in dyspeptic chlorosis it produces or accentuates a drug gastropathy. Since it is true that there is no part of the body which may not be the cause of cardiac palpitation, it is necessary to investigate all possible causes before attributing a lesion to the heart. Of these lesions which are accompanied by palpitation (acute aortitis at its commencement, acute endocarditis and pericarditis, pericardial adhesions, obstruction or insufficiency at the mitral valve), the symptoms of cardiac erethism are benefited by a pill of one and one-half grains of quinine hydrobromate, three-fourths of a grain each of powdered digitalis and extract of convallaria, twice to four times daily.—*Revue Générale de Clinique et de Thérapeutique.*

Treatment of Alcoholism.—Dr. N. S. Davis (*Quarterly Journal of Inebriety*, No. 2, p. 162, 1897) believes that the patient should be instructed in regard to deceptive and injurious influences of alcoholic drinks, so that he is actually convinced that their use is, on all occasions, unnecessary. The patient should be placed under good physical and social surroundings. For impaired digestion, irritable nervous system, and disturbed sleep, one-sixtieth of a grain of digitalin with one-thirtieth of a grain of strychnine at each meal, with from twenty to thirty minims of diluted hydrobromic acid at bedtime, will give excellent results. For constipation, thirty minims of fluid extract of rhamnus purshiana may be added to the acid. Instead of the digitalis and strychnine, a pill or capsule of a grain of extract of hyoscyamus, with three grains of cerium oxalate, may be given. Before an anticipated period of dissipation, a pill of two grains of quinine sulphate, the same amount of extract of eucalyptus globulus, and one-third of a grain of extract of cannabis indica should be given with each meal for two weeks. The patient should be separated from his associates, and if this cannot be done in any other way, he should reside in a well-regulated asylum for six to twelve months.

The Treatment of Graves' Disease.—Dr. Hector Mackenzie (*American Journal of the Medical Sciences*) speaks as follows in regard to the treatment of Graves' disease by means of thymus gland: "I am of opinion that the dose, to be of any use, should be at least one or two drachms a day, of the fresh gland or its equivalent in the form of extract or powder. The conclusion at which I have arrived is that the thymus gland possesses no specific action in Graves' disease. I have found it in most cases to have no effect either on the heart, on the goitre, or on the exophthalmos. At the same time it appears to be a remedy of some value, improving the general condition, and, in this way, may assist toward the recovery of the patient. I should, at present, place it in the same class of remedies as cod-liver oil."

Treatment of Burns.—The most exquisitely painful burns are assuaged in a few moments by an application of campho-phénique after the following formula:

℞ Cocaine hydrochlorate..... gr. v.
Campho-phénique..... ʒss.
Olive oil..... ʒss.
M. Rub up the cocaine and campho-phénique and add the olive oil.

A man whose hand had been torn and badly burned by an electrical discharge, the pain of which was so severe that he fainted twice before the dressing could be applied, expressed himself as absolutely without pain in less than one minute after the application.—*St. Louis Medical and Surgical Journal.*

Vermifuge for Children.—

℞ Benzonaphthol,
Santonine.....āā gr. xxx.
Sugar..... gr. lxxx.
M. Divide in twenty powders. S. Give two to five powders daily.

Obstinate Chronic Cough.—

℞ Tinct. sanguinariæ..... ʒ ij.
Antimonii et potassii tartratis..... gr. i.
Morphinæ sulph..... gr. ij.
Spir. anisi..... ʒ ss.
Glycerini..... ʒ ij.
Syr. simplicis.....q.s. ad ʒ iv.
M. S. ʒ i. q. 3 h.

—Dr. J. D. Ely, *Toledo Medical and Surgical Reporter.*

Pneumonia.—Silver nitrate, from 0.005 gm. to 0.015 gm. per diem, divided into ten doses in pill form.—Caccianiga, *Gazz. degli Osped.*, May 1st.

Pruritus Vulvæ.—

℞ Quininæ sulphatis..... 1.5
Menthol..... 0.5
Acidi carbolici..... 1.75
Ung. citrini..... 4
Ichthyoli..... 10
Lanolini..... 25
Olei castorei..... 40

—Beall.

Syphilis.—

℞ Alum. crud..... 5
Aquæ destill..... 500
Aquæ menth. piperitæ..... 30
M. S. Mouth wash.

—Dr. Julius Scheff.

Bronchitis.—

℞ Apomorph. hydrochlor..... 0.03
Morphinæ hydrochlor..... 0.02
Acidi hydrochlor. dil..... gtt. 5
Syr. aurantii cortic..... 15
M. S. To be taken in divided doses during the day.

—Neusser.

Pertussis.—

℞ Tinct. digitalis..... ♏ xvi.
Antipyrini..... gr. xxxij.
Tinct. opii camphor..... ʒ i.
Syr. tolutani..... q.s. ad ʒ ij.
M. S. ʒ i. three times a day.

—Koplik.

Dry Pleurisy.—

℞ Menthol..... 0.5
Cocainæ hydrochl.,
Morphinæ hydrochl ..... āā 0.1
Unguent. simpl..... 50
M. S. Apply twice daily.

—Neusser.

Tuberculous Laryngitis.—

℞ Carbolic acid..... 1–5 gm.
Lactic acid..... 2–15 "
Neutral glycerin..... 20 "
S. First anæsthetize affected parts with ten-per-cent. cocaine solution and then apply.

—Dr. R. Botey.

Decayed Tooth.—

℞ Crystallized carbolic acid..... 2 gm.
Oil of lemon..... 2 "
Alcohol, ninety per cent..... 10 "
S. Apply on cotton.

—Dr. S. Dunogier.

Acute Eczema.—

℞ Picric acid..... 3 parts.
Tepid boiled water..... 250 "
S. Apply locally.

—Dr. Paul Thièry.

Rickets.—

℞ Phosphori..... 0.1
Olei jecor. asel..... 100
M. S. Teaspoonful once daily.

—Kassowitz.

Vulvo-Vaginitis.—

℞ Aluminis,
Acidi carbolici..... āā 1
Aquæ fontis..... 100
M. S. Apply three times a day.

—Monti.

Aromatic Cod-Liver Oil.—

℞ Olei jecor. asel..... 400 gm.
Syr. bals. tolutan..... 200 gm.
Tinct. bals. tolutan..... gtt. xij.
Tinct. caryophyl..... gtt. ij.
S. Shake well before using.

—Bricemoret, *Gaz. Hebdomad.*, No. 15, 1898.

Insomnia of Alcoholic Pneumonia.—

℞ Codeine..... gr. ij.–iv.
Elix. chloralamide..... (gr. xx.–ʒ ss.) ʒ ij.
M. S. Tablespoonful, to be repeated if necessary every two hours until three doses are taken.

—A. A. Smith.

Severe Syphilis.—

℞ Iodine..... 1
Potassii iodidi..... q. s.
Glycerin, neutral..... 5–10
Acidi citrici..... 15
Syr. simplicis..... 1,000
M. S. ʒ i.–ix. daily, half-hour before meals.

—Bouveyron, *Lyon Médical, 2, 1898.*

Pruritus Scroti.—

℞ Hydrar. chlor. corrosiv..... 0.05
Alcohol,
Aquæ chamomill..... āā 25
Chloroformi..... gtt. 5
Aquæ laurocerasi..... q.s. ad 100
S. Use as a wash.

—Leistikow.

Habitual Constipation.—

℞ Podophyllini..... 0.5
Extr. aloes,
Ext. rhei..... āā 3
Ext. taraxaci..... q.s.
M. ft. pill. No. xl. S. One or two pills before retiring.

—Nothnagel, *Zeitschrift für Krankenpflege*, April, 1898.

Polyarthritis Rheumatica.—

℞ Salipyrin..... 6
Glycerini..... 14
Aquæ destill..... 40
Syr. rub. idæi..... 30
M. S. Tablespoonful every hour.

—Kölbl, *Allgemeine Wiener Mediz.-Zeitung*, Nos. 5 and 6, 1898.

Diffluvium Capillorum.—

℞ Resorcini,
Quininæ sulphatis..... āā gr. xx.
Tinct. cantharid.,
Tinct. capsici..... āā ʒ i.
Vaselini..... ʒ i.
M. S. Rub ʒ ss. into scalp daily.

Pertussis.—

℞ Phenocol hydrochloride,
Antipyrin..... āā gr. viiss.
Potassium bromide..... gr. vi.
Syrup of bitter-orange peel,
Orange-flower water..... āā q.s.
M. S. Divide into four doses and give all in twenty-four hours to a child of eight years.

—Guaita.

Hemorrhoidal Conditions during Pregnancy.—

℞ Potassii bitartratis,
Sulphur. præcipitatis..... āā p. æ.
M. S. ʒ i. twice daily.

—Da Costa.

Acute Bronchitis.—

℞ Ammonium chloride..... ʒ iij.
Comp. syrup of squill..... ʒ vi.
Syrup of wild cherry..... q.s. ad ʒ iij.
M. S. Teaspoonful every three hours.

—Eshner.

Chronic Conjunctivitis.—

℞ Acidi tannici..... gr. ij.–iv.
Sodii biboratis..... ʒ i.
Glycerini..... ʒ ij.
Aquæ camphoræ..... ʒ iv.
M. S. External use.

Or:

℞ Ichthyol..... ♏ xx.
Aquæ sambuci,
Aquæ destill..... āā ʒ ij.

—Berry, *Medical News*, January, 1898.

Pharyngitis Sicca.—

℞ Acidi carbolici..... ʒ i.
Tinct. iodi..... ♏ v.
Tinct. opii..... ♏ vij.
Tinct. aloes..... gtt. x.
Glycerini..... ʒ i.
M. S. Apply to the pharynx thrice daily by means of an atomizer.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 24, 1898:

	Cases.	Deaths.
Tuberculosis	133	146
Typhoid fever	167	29
Scarlet fever	59	3
Measles	41	3
Diphtheria	109	17
Cerebro-spinal meningitis	0	5
Laryngeal diphtheria (croup)	6	3

Tight Lacing.—Dr. W. E. Fitch read a paper with this title before the Georgia Medical Association, on April 21st, upon the relation of tight lacing to uterine development and to diseases of the female organs of generation, in which it is stated that "Africans, Indians, and all other people who wear loose clothing are almost entirely free from pelvic disorders. It is in this class of women that we find the most natural and perfect pregnancy, the easiest and most natural deliveries, and the most satisfactory puerperium."

Infectious Diseases tend to get well of their own accord; that is, the inherent forces of the tissues themselves are generally sufficient to overcome the infection and prevent any great disorder of nutrition, when the infection is not too great. When the infection is too great, disorders of nutrition are produced, and we find the tendency toward the production of fibrous tissue increased, as we see well illustrated in the sequelæ of scarlet fever, typhoid fever, tuberculosis, and other diseases. Everything seems to prove that syphilis is undoubtedly an infectious disease, and yet one of its most startling anatomic features is the increase of fibrous tissue, which suggests the doubt as to the complete curability of the disease. —Ernest F. Tucker.

Erroneous Habits of Eating.—I have come to the conclusion that more than half the disease which embitters the middle and latter part of life is due to avoidable errors of diet; and that more mischief, in the form of actual disease, of impaired vigor, and of shortened life, accrues to civilized man from erroneous habits of eating than from the habitual use of alcoholic drink, considerable as I know that evil to be.—Sir Henry Thompson.

Professional Secrecy.—A physician in France was recently fined for refusing to testify to the circumstances of an altercation which he had witnessed between husband and wife on the occasion of a visit which he made in his professional capacity. The quarrel occurred immediately upon his arrival, and he went away without either prescribing or giving any medical advice whatever. For this reason the divorce court held that he was absolved from all obligations of professional secrecy, and was bound to disclose what he saw, just as any non-professional witness would be. He contended, on the other hand, that inasmuch as he had been summoned solely as a medical adviser, his presence at the scene was wholly due to his professional character, and that if he had not been there as a doctor he would not have been there at all, in which event he would have had nothing to tell. The smallness of the fine imposed, which was only ten francs, indicates that the court did not deem his refusal to testify a very heinous offence, and before he was compelled to give the desired evidence the case was settled.—*New York Sun*, September 18th.

A Layman's Imaginative Mind.—I remember going to the British Museum one day to read up the treatment for some slight ailment of which I had a touch—hay fever, I fancy it was. I got down the book and read all I came to read; and then, in an unthinking moment, I idly turned the leaves and began indolently to study diseases generally. I forget which was the first distemper I plunged into—some fearful devastating scourge I know—and before I had glanced half way down the list of "premonitory symptoms" it was borne in upon me that I had fairly got it. I sat for a while, frozen with horror; and then, in the listlessness of despair, I again turned over the pages. I came to typhoid fever, read the symptoms, discovered that I had typhoid fever; must have had it for months, without knowing it; wondered what else I had got. Turned to St. Vitus' dance; found, as I expected, that I had that, too; began to get interested in my case, and determined to sift it to the bottom. And so I started alphabetically, read up ague, and learned that I was sickening for it, and that the acute stage would commence in about another fortnight. Bright's disease, I was relieved to find, I had only in a modified form, and, so far as that was concerned, I might live for years. Cholera I had with severe complications; and diphtheria I seemed to have been born with. I plodded conscientiously through the twenty-six letters, and the only malady I could conclude I had not got was housemaid's knee.—Jerome K. Jerome, "Three Men in a Boat."

Sudden Death in Children.—Sudden death of apparently healthy children, according to Dr. Bertholl (*Archiv für Kinderheilkunde*, No. xxiv., 1898), is usually due to acute or subacute hyperplasia of the thymus gland. He concludes as follows: (1) In spite of opposing views, the existence of an idiopathic hypertrophy of the thymus, capable of bringing about the death of an infant, has been demonstrated. (2) A swollen thymus gland, in association with rachitis and the status lymphaticus, may also play an important rôle in the sudden death of children during an attack of laryngismus stridulus. (3) Finally, an acute lordotic flexion of the neck may compress the trachea in such a manner that sudden death by asphyxia can take place.—*Pediatrics*, June 15th.

The Disinfection of Rooms.—Novy and Waite (*Medical News*, May 21st) conclude a paper upon the above subject with the following general directions:. (1) All cracks or openings in the plaster or in the floor or about the door and windows should be caulked tight with cotton or with strips of cloth. (2) The linen, quilts, blankets, carpets, etc., should be stretched out on a line in order to expose as much surface to the disinfectant as possible. They should not be thrown into a heap. Books should be suspended by their covers, so that the pages will fall open and be freely exposed. (3) The walls and floor of the room and the articles contained in it should be thoroughly sprayed with water. If masses of matter or sputum are dried down on the floor, they should be soaked with water and loosened. No vessel of water should, however, be allowed to remain in the room. (4) One hundred and fifty centimetres (five ounces) of the commercial forty-per-cent. solution of formalin for each one thousand cubic feet of space should be placed in the distilling apparatus and be as rapidly distilled as possible. The keyhole and spaces about the door should then be packed with cotton or cloth. (5) The room thus treated should remain closed at least ten hours. If there is much leakage of gas into the surrounding rooms, a second or third injection of formaldehyde at intervals of two or three hours should be made.

The Bengalee have no lunulæ. Jews as a rule have large ones. In Greeks the thumb only has one.

The Discovery of America.—The *Medical Age* calls attention to the part played by a physician, Dr. Paolo Toscanelli, of Florence, Italy, in the following terms: "The Spaniards are probably asking themselves what on earth possessed Christopher Columbus that on an evil day he should have discovered America. Now that everything Spanish is to be reprobated, it is satisfactory to find that, while Columbus actually discovered the western continent, the existence of it and the way of reaching it were suggested to him by a Florentine doctor named Paolo Toscanelli. The truth seems to be, according to Professor De Lollis, that Columbus placed himself in communication with Toscanelli in 1479, and that Toscanelli provided Columbus with a map which guided the discoverer in his voyage. Columbus, in his log of the ship, admits the service that Toscanelli performed. The Florentines are about to celebrate the part Dr. Toscanelli performed in the discovery of the western continent."

Roentgen Skiagram in Persistence of Ductus Botalli.—In a case presented a short time ago to the Berlin Society for Internal Medicine, the diagnosis of a persistent ductus Botalli was confirmed by an *x*-ray picture. Gerhardt has pointed out that there is in such cases an area of dulness above the base of the heart to the left of the sternum. This is considered to be due to the dilated pulmonary artery. In this case a distinct shadow was found in this situation in the Roentgen skiagram. This, too, is typical of the Zeitgeist in Germany, for, while scarcely a surgeon makes a diagnosis of a fracture without a skiagram, no internist concludes definitely as to the presence of an aneurism without the same aid, and even invokes it at times for tuberculous infiltration of the lungs and other intrathoracic conditions.—*Philadelphia Medical Journal.*

For the Removal of Nitrate-of-Silver Stains from Clothing.—A solution of iodine in ammonia water, the so-called colorless tincture, will remove nitrate-of-silver stains from the hands, clothing, etc., but, owing to the danger of the formation of nitrogen iodide, which is a powerful explosive, it is not recommended. A solution of iodine in iodide of potassium dissolved in water is nearly as quick and quite as effective. Dissolve fifteen parts of iodide of potassium in fifty parts of water, and to the solution add ten parts of iodine. When the latter is dissolved add sufficient water to make five hundred parts. Keep in a well-stoppered bottle. Treat the spots with this, and after a few minutes with a ten-per-cent. solution of caustic soda, which will remove the silver iodide formed by the first treatment.—*National Druggist.*

What Constitutes a Liberal Education.—That man has a liberal education who has been so trained in youth that his body is the ready servant of his will, and does with will and pleasure all the work that, as a mechanism, it is capable of; whose intellect is a clear, cold, logic engine, with all its parts of equal strength, and in smooth working order, ready, like the steam engine, to be turned to any kind of work, and spin the gossamers as well as forge the anchors of the mind; whose mind is stored with the knowledge of the great and fundamental truths of nature and of the laws of her operations; one who, no stunted ascetic, is full of life and fire, but whose passions are trained to come to a halt by a vigorous will, the servant of a tender conscience; who has learned to love all beauty, whether of nature or art, to hate all vileness, and to respect others as himself. Such a one, and no other, has had a liberal education.—Huxley.

Modern Medical Students learn surgery, which but few practice; nearly all practise obstetrics, which few learn.—Sinclair.

Compensation in Cases of Appendicitis.—The experienced and really capable physician is entitled to a fee proportionately important to that which surgery expects, when the equivalent in service is rendered. Medical treatment strives to save and prolong human life, and when the result to the patient is the same, whether through the assistance of surgeon or of physician, why need the fee be widely different? The fee of $500 to $5,000 may or may not be too much for an appendectomy, but if the same end is safely and satisfactorily attained by the practitioner, why should his fee be less than that of his surgical contemporary? When the emoluments for medical work, skilfully and successully accomplished, whether by surgeon or by physician, are relatively similar, there will be an incentive for closer co-operation, higher medical thought, and better treatment than prevails in some places at this time. The practitioner is entitled to the full equivalent in exchange for intelligently performed services in the conservation of human life, and that equivalent should correspond to the measure of success in each case treated, with a proper and due regard for the skill, experience, and years in medical practice.—Dr. Elmer Lee, *Journal of the American Medical Association*, September 10, 1898.

Masturbation and Insanity.—Of all sexual conditions complicating insanity, none occupies the importance, either in the professional or the lay mind, that masturbation holds. It is a vice of most frequent occurrence among our sane population, and it is almost universally practised by the insane. That masturbation alone, in the normal individual, produces insanity, is certainly not true; for were this the fact, the accommodations of our asylums would have to be so increased as to hold at least five hundred thousand, rather than the five thousand insane credited to our State.—Dr. J. W. Robertson, *Pacific Medical Journal*, September, 1898.

Laughter is one of the greatest helps to the digestion with which I am acquainted, and the custom prevalent among our forefathers of exciting it at table by jesters and buffoons was founded upon true medical principles.—Hufeland.

Health Reports.—The following statistics concerning small-pox, yellow fever, cholera, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending September 24, 1898:

Small-Pox—United States.

		Cases.	Deaths.
Alabama, Dwight	August 1st to September 12th..	12	1
Kansas, Pawnee	September 15th	1	
Virginia, Norfolk	September 20th	2	

Small-Pox—Foreign.

China, Hong Kong	July 31st to August 6th	1	
England, London	August 27th to September 3d ..	2	
India, Madras	August 6th to 12th	1	
Russia, St. Petersburg	August 13th to 20th	1	
St. Petersburg	August 20th to 27th	1	
Uruguay, Montevideo	July 31st to August 6th	1	

Yellow Fever—United States.

Louisiana, Franklin	To date	70	2

CONTUSED WOUNDS OF THE ABDOMEN AND THEIR SURGICAL TREATMENT.[1]

BY JOHN T. ROGERS, M.D.,

CLINICAL INSTRUCTOR IN SURGERY, UNIVERSITY OF MINNESOTA, ST. PAUL, MINN.

THE erect posture of man and the inadequate protection afforded to the viscera by the abdominal walls subject the abdominal contents to various injuries, not the least infrequent of which are abdominal contusions. Our text-books dismiss the subject with unsatisfactory instructions as to diagnosis, symptoms, and treatment, some authors even failing to mention that contusions of the abdomen ever occur. The literature of the present day is likewise incomplete and unsatisfactory in its treatment of this condition. That more cases are not reported in our journals is, I believe, due to the fact that almost all grave contusions of the abdomen result fatally, and we are very loath to report our unfavorable cases, even to the medical profession. The writer hopes that the discussion of his paper will bring forth the reports of many cases which he feels sure have occurred in the practice of the members of this society. My object will have been accomplished if I succeed in interesting you sufficiently to induce you to report your cases, not only to the society but to the journals, thus enabling the profession at large better to understand this condition, and to treat it more intelligently than has been done in the past. Reports of cases with comments by experienced men are, to my mind, better educators on any surgical subject than lengthy articles based upon theoretical knowledge.

Abdominal contusions most often result from kicks from beast or man, blows with blunt instruments, squeezing between two heavy bodies, and, from the nature of their occupation, lumbermen in the woods or saw-millsare frequently the recipients of such injuries.

Symptoms.—From the very extensive distribution of the sympathetics to the abdominal contents, it would be but natural to expect to have shock as a symptom of prime importance. That there are exceptional cases in which no shock is manifest only goes to prove the rule. It is present in nearly every case to a greater or less degree, depending upon the nature of the injury, its location, the character of the vulnerating force, and upon the condition of the abdominal wall and contents of the abdomen at the time of injury. A blow applied directly over the solar plexus always causes a great degree of shock, and has been known to produce death, without injury to the abdominal wall or to the contents of the abdomen. In many cases there is no external evidence of violence to the abdominal wall, or, when present, may be of so slight a nature as to cause little or no attention.

On the other hand, there may be extensive contusion and laceration of the abdominal walls, without injury to the contents of the abdomen. Severe pain, nausea, and vomiting, immediately following or accompanying shock, may be taken as evidence of grave abdominal injury. Obstipation is usually marked.

Great anxiety, restlessness, and fear of impending death are pronounced. Bryant, Hitchcock, and Lambert each report a case in which none of these symptoms were present. The patients in each instance walked for a considerable distance with their intestinal contents in the peritoneal cavity. Usually, however, the pain is excruciating, especially at the seat of injury. Vomiting is continuous. There are great prostration, lividity of lips, and extreme pallor; the pulse is small, rapid, and irregular; respiration is shallow; there are subnormal temperature, leaky skin, and rapidly developing tympanites, due to intestinal paralysis or to the escape of gas from the intestine. Extreme rigidity of the abdominal walls is, perhaps, the most important and characteristic symptom. It is present in every case and may be considered almost pathognomonic of grave intra-abdominal lesion. Deaver says he has seen this condition so pronounced as to call to mind the checkerboard appearance of the normal abdominal walls as represented by artists of former times. In those cases which I shall report later (all of which were fatal), this boardy condition was present in a marked degree. The character of the vomiting was varied from the simple expulsion of the stomach contents to the most violent retching or regurgitation of the intestinal contents, always an evidence of grave abdominal lesions.

Pathology.—Contusions of the abdomen may produce lesions of any of the abdominal viscera. The alimentary tract, being least protected, is most often the seat of grave injury. Seventy-five per cent. of these lesions occur in the small intestines, the rupture usually taking place outside of the mesenteric attachment. It is generally conceded to be due to squeezing of the intestine between the compressed abdominal wall and the vertebral column. Intestines distended with gas or fæces are more apt to be injured than is the collapsed bowel.

Diagnosis.—The chief points to be considered in making the diagnosis of grave intra-abdominal lesions are the history of the injury, location of the injury, character of the vulnerating force, rigidity or boardy condition of the abdominal walls, obstipation, vomiting, pain, anxiety, and restlessness, the degree of shock and prostration. The pulse and temperature, while not to be depended upon in making a diagnosis, may be taken as reasonably safe guides in making a prognosis. Depending upon the degree of shock, the pulse is at first rapid, irregular, and weak; temperature, subnormal or normal. In favorable cases the pulse becomes stronger and regular, temperature normal or above normal. In unfavorable cases the pulse continues weak, intermittent, becoming hard and wiry; temperature fails to reach normal, or there rapidly supervenes a condition of hyperpyrexia. If there be as a result of the contusion lesions of abdominal viscera other than the intestinal tract, the symptoms will be chiefly those of internal hemorrhage, and the various other symptoms referable to the particular organ injured. A detailed description of injuries to the liver, kidneys, spleen, pancreas, mesentery, or omentum and bladder would require too much time to discuss here. Thomas Bryant, in the London *Lancet*,

[1] Read before the Minnesota State Society, at the annual meeting in St. Paul, June 15, 16, and 17, 1898.

December 7, 1898, says: "The character of the force and the mode of its application always appear to be of much value as a help to diagnosis in most cases of intestinal injury, for it would seem that when the force is of a diffused rather than a localized character the injury is more likely to be extensive, or even double. Thus, when a human being is run over, the wheel of a vehicle passing over the abdomen or the back, with the abdomen downward; when he falls from a height, upon a plank or beam; is trodden on by a horse, or is crushed between two obtuse bodies, it is more probable that a solid viscus has been lacerated or that some portion of the small intestine has been torn in one or more places."

Statistics in 149 cases, in which various degrees of rupture of the intestinal tract had occurred, give clearly the history of 80 of these cases. Thirty-six cases were due to horse kicks, 23 to carriage wheels, 13 to kicks from men, and 8 from spent shell fragments or bullets.[1]

Course and Prognosis.—Without immediate surgical interference I believe that not one in one hundred cases of severe abdominal contusion ends in recovery. Sajous' "Annual" puts the mortality at ninety-six per cent. Without operation these patients when they recover from the primary shock, rapidly develop septic general peritonitis and die, or else, especially in injuries to the liver and spleen, they die of hemorrhage. Rupture of one kidney when the other is normal may result in recovery. Rupture of the bladder results fatally if early operation and drainage are not resorted to.

Treatment.—My experience with abdominal contusions and a careful study of all the literature at my disposal teach me to say unhesitatingly that the most conservative treatment is early operation, and I mean by "early operation" as soon after the receipt of the injury as possible; immediately, if the patient is not in collapse. The advances in modern surgery have made it possible to explore the abdomen with impunity, and with almost absolute safety. I believe it is better surgery to open the abdomen in doubtful cases and find no lesion, than to wait in a single instance until signs of septic peritonitis are present. An aseptic exploration will do no harm, while delay means death in ninety-six per cent. of all cases of rupture of the intestine.

The patient should be as carefully prepared as rapidity of action will allow, and a free incision made in the median line and the injured organ located as quickly as possible. Oftentimes this is a difficult procedure. In locating the seat of injury it is important to bear in mind the exact point at which the violence was applied. Immediately upon an injury of this character there is a paralysis of the bowels, and in most cases the rupture will be found immediately beneath the point where the vulnerating force came in contact with the abdominal wall. Of further importance, I believe, is the action of the omentum, especially in those cases in which considerable time has elapsed after the receipt of the injury. It seems to me that in many, if not all, cases of rupture or injury to the viscera, the omentum throws itself into the breach, and endeavors, by adhering to the wounded organ, to protect the general cavity from infection. A large portion of the omentum will be found adherent at the point of rupture. If this is a fact, you can readily see that it would add much to our ease in locating the injury. Prognosis is much more unfavorable if it becomes necessary in any case to expose the intestinal coils. However careful we may be to keep them protected by hot towels, this procedure adds much to the shock of the operation; so much, indeed, that death almost invariably occurs when evisceration is necessary. I doubt exceedingly whether such a procedure is ever necessary, or whether ever justifiable.

[1] Charassi, French Congress of Surgeons, 1885.

After the ruptured intestine is found, pull out only so much as is required for rapid closure of the rent; close it in the usual way, remove all septic material possible by carefully mopping out the cavity with soft gauze sponges.

When nature has had no opportunity to wall off the septic area it seems proper and becomes a great temptation to irrigate the cavity with warm saline solution. But if we stop for a moment to consider briefly the physiology of the peritoneum in its relations to absorption, I think it will be seen that irrigation under these circumstances is an unsurgical procedure. Byron Robinson's conclusions, based upon a thorough study of the subject and much personal experimentation, are as follows:

"1st. The primary path by which fluids pass from the peritoneum into the circulation is by way of the lymphatics. The secondary path is the blood-vessels.

"2d. A stream of fluid exists in the peritoneum directed toward the diaphragm.

"3d. The anatomical structure and physiologic function (respiration) of the diaphragm enable it to act like a suction and a force pump.

"4th. In five minutes after injection into the abdomen of a solution holding Berlin blue in suspension, the colored granules may be found in the subdiaphragmatic lymph bed and intrathoracic glands.

"5th. So far as my experiments extend, the diaphragm is the primary locality of peritoneal absorption of solid granules. Others assert that the rootlets of the portal veins also absorb fluid, but I have not been able to confirm the correctness of the assertion.

"6th. The vast function of absorption performed by the diaphragm and the very small part taken in this process by other portions of the peritoneum account for the non-fatality in the purulent conditions found at the tubal ends and about the appendix and the ruptured gall bladder, which is circumscribed and confined by the ligamentum hepatico-colicum. The virulent microbes or their products are not absorbed but circumscribed."

On account of vigorous absorptive powers, the nearer peritonitis approaches the diaphragm the more dangerous it is to life. Practical experience in irrigating in cases of septic peritonitis convinces me that it should be abandoned. Gently mopping out the cavity and thorough gauze drainage will give better results. If the liver has been ruptured our efforts of course will be directed to controlling hemorrhage, which is best done by packing. The same is true for ruptured spleen, when there is only a slight tear. Rapidly fatal hemorrhage supervenes when the rupture is extensive. Owing to the fact that both kidneys are rarely affected by the same force, injuries to these organs are not so fatal in their results. When laceration is not extensive and hemorrhage is not severe, recovery may take place without surgical interference. If, however, the shock has been great and there be present evidence of great laceration of one kidney, nephrotomy and drainage, or nephrectomy is indicated. Rupture of the bladder, intraperitoneally or extraperitoneally, requires immediate operation for repairs and drainage. I consider the suprapubic method the best procedure. In all operations for the repair of injuries of the abdominal viscera there is great shock, and it becomes our duty to minimize this element by every means in our power. We should operate rapidly, the room should be kept at a proper temperature, hot-water bottles or bags should be constantly applied, even in the warmest room. Infusion or hypodermoclysis with decinormal saline solution is almost always indicated, both during and after operation. Repeated infusions may occasionally carry a desperate case over a period of shock. The after-treatment of these cases is the same as for an ordinary laparotomy.

Report of Cases.—Case I.—Mr. A——, Swede, occupation, moulder; good habits. At the time of admission to Dr. C. A. Wheaton's service at the City and County Hospital, he was in general appearance very much emaciated. Face pinched and anxious, eyes sunken, skin dry, tongue dry and coated. Very weak; persistent diarrhœa; pain in abdomen very severe; great rigidity of abdominal wall. Temperature, 97.8° F.; pulse, 85; breathing labored. Abdomen retracted and very tender on palpation. Temperature remained between 97° and 97.5° F., pulse 80 and 85, during his stay in the hospital. Stools yellow and watery and very offensive in odor; no emesis. Admitted January 30, 1898. On January 20th, while feeding a buzz saw, a board thrown back from the saw struck him across the abdomen, necessitating his quitting work and removal to his home. He says he was very weak at the time, but did not suffer much pain until evening, when vomiting ceased. It commenced again on the following day and had been persistent since. Diagnosis, intestinal gangrene with localized peritonitis. Death occurred February 1st.

Case II.—Mr. B——, admitted to the service of Dr. C. A. Wheaton, October 25, 1898; aged thirty-seven years; male, white, English; occupation, veterinary surgeon; habits good. Three days previous to admission while operating on a horse, he was kicked in the left hypochondriac region. No external injury. Watch case slightly indented. Hiccough commenced immediately after the injury, and was incessant except during a few snatches of sleep. No gas passed per rectum. Stercoraceous vomiting commenced the following day. On admission hiccoughing, complete obstruction of the bowels; intermittent stercoraceous vomiting; abdomen markedly distended, rigid, and tender; tympanitic from level of the umbilicus on either side downward. Temperature, 98° F.; pulse, 120. At 7 P.M. he was taken to the operating-room and abdominal section was made by Dr. C. A. Wheaton. Cavity filled with a pea-soup material, fæcal in odor. Intestines injected. Small intestine picked up and inspected and a couple of perforations found. Some deposits of lymph about them. These were closed with three rows of Lembert sutures. Cavity flushed out with saline solution. Patient moribund when taken from operating-room. Abdomen closed with interrupted wire sutures. Death occurred about two minutes after removal from operating-room.

Case III.—Mr. C——, laborer, aged twenty-five years; white, American; habits good. Admitted to hospital March 26, 1898. At the time of admission he was a well-developed, rugged man. Mental condition good. Beween four and five o'clock on the afternoon of admission he was kicked in the left upper quadrant of the abdomen by a horse, which caused sufficient pain and shock to cause him to lie down, but did not render him unconscious. A physician was called and gave an opiate. The man was sent to the hospital. On admission at 11 P.M. he was in great pain; shock severe. Pain continued to be very severe; vomiting; no passage of gas or fæcal matter, abdomen rigid and tense; tympanites not marked; great pain to the left and below the umbilicus. At 2 P.M. I made an abdominal section and found a couple of lacerations in the jejunum near the duodenal junction. Ruptures repaired; cavity irrigated with decinormal saline solution, drained, and closed with interrupted sutures. Patient suffered severe shock following operation; transfusion of saline solution rallied him for a while, but only temporarily. Died at 1:15 A.M., March 28. Diagnosis, rupture of intestine, general peritonitis.

Case IV.—Dr. D——, white, aged thirty-five years; large, well-developed man. Was coasting down hill in front of a bobsled. When two-thirds of the way down, while going at a terrific rate of speed, he struck another bobsled, which was being drawn across the path. He was unconscious for a few minutes after the receipt of the injury. I saw the patient within fifteen minutes after injury. He was then suffering excruciating pain. Pallor extreme, skin leaky, severe shock. He was removed to the hospital. Pain continued; vomiting; pulse became intermittent and weak; distention of abdomen, complete obstipation, great tenderness and rigidity of abdomen. No external evidence of violence. Great restlessness and anxiety. Temperature subnormal; respiration shallow and labored. Died on the third day. Diagnosis, general septic peritonitis, probable rupture of the intestines. No operation; no post-mortem.

THE BLOOD IN SEPTIC DISEASES OF THE ABDOMEN AND PELVIS.[1]

By HERBERT MAXON KING, M.D.,

PHYSICIAN TO BUTTERWORTH HOSPITAL, GRAND RAPIDS, MICH.

It is true that for the greater part a consideration of the subject which has been given me in this discussion must as yet be confined to a record of observations. Time, your patience, and my own inclinations prevent any elaboration of theories; and the pathological phenomena observed in the blood in many diseases, among them septicæmia in its various manifestations, can at present be studied only as a series of interesting facts, valuable, to be sure, to the clinician, but still not wholly satisfactory from a scientific point of view to the pathologist. I shall, however, attempt briefly to show a few of the practical advantages accruing to the practitioner from examinations of the blood in the diseases under discussion.

There are generally recognized three distinct degrees, if not kinds, of sepsis, in each one of which the blood presents certain modifications, not always, however, sufficiently marked to make differential diagnosis a matter of certainty.

The first and mildest form, by Bergmann termed "fermentative fever," by Volkmann "aseptic or resorption fever," and by Matthews Duncan "sapræmia," is by many thought to be in reality a very mild sepsis, in which for unknown reasons the pathogenic micro-organisms are least virulent, or in which conditions in the body are such as to overcome immediately all toxic effects and to resist development of absorption of further toxic material. Such so-called reaction as attends absorption of small blood clots, post-operative or following extravasation of blood from contusions, or perhaps the slight febrile reaction occasionally following parturition, subsiding within a few hours and with no untoward results, are all representative of this form of sepsis.

In these cases the blood is least often studied. The few observations which I have made show no departure from normal save in the mild leucocytosis subsiding almost entirely with the febrile reaction.

The second form or degree is that most often met with, the one in which the reaction in the blood is most marked and characteristic and in which the natural course tends to recovery, but which by long continuance of the septic leak into the circulation or the supervention of the third and most malignant form not rarely terminates fatally. This is a septic intoxication due to the entrance into the circulation of the toxic products of pyogenic organisms, but not to any extent of the organisms themselves. This is the common puerperal sepsis ending in recovery, or an appendicitis in which the inflammatory focus remains

[1] Part of the general discussion on "Septic Diseases of the Abdomen and Pelvis," before the Michigan State Medical Society at the annual meeting in Detroit, May 5 and 6, 1898.

localized, or the common form terminating in recovery following abdominal section, etc. Such a sepsis may be immediately fatal if a sufficient quantity of the toxin is introduced suddenly into the circulation; such a case is not marked to any extent by demonstrable changes in the blood during life, the system being overwhelmed before leucocytosis can occur or the hæmatogenic functions become operative. And aside from the diminution in fibrin threads and the imperfect formation of rouleaux as seen in the fresh specimen before drying, as well as the imperfect formation of the clot, I know of no demonstrable antemortem blood changes.

When, however, the amount of intoxication is insufficient to cause death immediately, the reaction as determined in the blood is most characteristic; and it is a description of such a blood condition that I shall endeavor to give below, as the most typical illustration of septic blood, from which the mild and transient leucocytosis of "fermentative fever" and the almost negative reaction of the more severe true septicæmias are merely in degree departures from the standard.

True septicæmia constitutes the third form or degree of sepsis, so to speak, and is distinguished from the other forms by the entrance into the circulation of sufficient numbers of pyogenic organisms themselves to overcome resistance, either in the form of phagocytosis or antitoxæmia. Such an invasion constitutes a progressive and malignant form of true septic infection, the blood being transformed into an unresisting culture medium, and death inevitably following, as in the case of anthrax, which is the type of true septicæmia. Here the most interesting feature in the study of blood is, of course, its bacteriology. If the infection is gradual or one in which the micro-organism is of the less pathogenic variety, a rise in the leucocyte count will follow and continue in varying degree until resistance is overcome or the source of infection is removed. It is possible that under certain conditions the count might rise as high as in any form of sepsis; but in my experience, which has been limited to observations in two cases of this character (both instances of rupture of a suppurating appendix into the general peritoneal cavity), the highest count was eighteen thousand to the cubic millimetre, death occurring within six hours thereafter and before another blood examination was possible.

In septic intoxication due to obscure pus foci, when drainage is for any cause imperfect, a more or less constant invasion of the circulation by toxic products results in a rapid and often extreme anæmia, both in destruction of red cells and in loss of hæmoglobin. As Roscher has shown, anæmia appears earlier and is more pronounced in sepsis than in any other of the infectious diseases.[1] The blood is thus less resistant and consequently more liable to sudden invasion by and development of the micro-organisms, resulting quickly in death, or by continued attenuation of the circulating fluid, due to the toxæmia alone. Death from exhaustion may occur without even a perceptible rise in the leucocyte count. Such a picture is most often seen at the close of pulmonary consumption, when a prolonged septic fever masks the tuberculous process and becomes the cause of death, and may be witnessed often in those obscure and chronic suppurating diseases of the pelvis and abdomen.

In acute septic intoxication of pelvic or abdominal origin, as following laparotomy; in the formation and retention of pus, as in appendicitis or perinephritic abscess in a patient previously healthy, with the first rise of temperature and pulse, an examination of the peripheral blood will reveal a condition not far removed from the following, which I offer as a type:

[1] Inaug. Dissert., Berlin, 1894.

Blood examination within the first six hours of initial septic intoxication:

General appearance. (1) Flows easily from finger or ear (whichever is employed in the observation). (2) Coagulum forms rather slowly, but the contraction (as observed in the small glass vessels used by Hayem for this purpose) is practically normal, both as to shape and relation to serum. (3) The serum presents no departure from normal.

Fresh specimens under the microscope. (1) Rouleaux normal in length and number of composing erythrocytes. (2) Spaces of normal size. (3) "Hæmatoblasts" appear in normal number and arrangement. (4) Fibrin threads from the first appear fewer and more deliberate in formation—what Hayem would designate "second degree." (5) Neither in shape nor in size do erythrocytes show departure from normal. (6) Leucocytes appear in excess and phagocytic motility is more apparent than normal.

Dry unstained specimen. Shows no departure from normal, except in excessive number of leucocytes.

Stained specimen. (1) Shows no departure from normal in erythrocytes. (2) Leucocytes show the following relative proportion between the varieties: Small lymphocytes, 11 per cent.; large lymphocytes, 5; polymorphonuclear neutrophiles, 78; eosinophiles, 3; large mononuclear or transitional forms, 3. Aside from a slight relative increase in polymorphonuclear neutrophiles this would be a normal relation.

Quantitatively. Erythrocytes, 4,500,000 to one cubic millimetre; leucocytes, 15,000 to one cubic millimetre; hæmoglobin, 70 per cent.; color index, 0.77.

The only practical departure from normal in this specimen is seen to be a very moderate leucocytosis (the low hæmoglobin percentage is probably of more or less long standing and has little or no connection with the sepsis). The increased number of leucocytes, however, is not more than is often remarked in a digestion leucocytosis, except that such error has been eliminated by choice of time of examination. The case might appear, so far as the blood is concerned, a very mild intoxication; possibly even a fermentative fever.

In the case from which this illustration is drawn, one of pelvic abscess, operation was deferred twenty-four hours, when another examination of the blood was made, temperature and pulse remaining practically unchanged, and other conditions as nearly identical with the first examination as possible. At this second examination the following points of difference in the blood are manifest: (1) The serum is perceptibly more watery; (2) "hæmatoblasts" are less numerous; (3) fibrin threads are fewer; (4) leucocytes are much more numerous, as estimated in the fresh unstained specimen; (5) the stained preparation shows like apparent increase in leucocytes, while the proportion between the different varieties shows no important change from that at the first examination; (6) quantitatively erythrocytes have fallen to 4,000,000 in one cubic millimetre; leucocytes have risen to 32,000 in one cubic millimetre. Hæmoglobin remains at 70 per cent.; the color index is raised to 0.87.

Operation at this time was partially successful in securing drainage. Leucocyte counts immediately following operation and at intervals of several days thereafter at first showed marked diminution, falling as low as 10,000; but following with more or less regularity the waves of temperature and pulse, they rose again to 35,000, when second operation secured free drainage, and within two days the leucocytes were within normal range.

Meanwhile, in scarcely a month that the case was under observation, attenuation of the blood as a whole had progressed with remarkable steadiness and ra-

pidity, red cells falling to two and one-half millions to the cubic millimetre and hæmoglobin to forty per cent.

This I think may be fairly taken as a type of the phenomena observed in the blood in an ordinary case of sepsis, resulting in recovery after some delay.

During the course of such a case, if the leucocyte count had suddenly and without due cause (as, for instance, the establishment of perfect drainage) fallen to normal or below, it would have been a bad prognostic sign, as Cabot and others have pointed out, indicating an overwhelming of the system by a sudden and severe general infection.

A sudden and radical rise in leucocyte count would, on the other hand, have indicated an extension of the suppurating process into previously uninvaded tissue without general absorption of infecting material, while a gradual diminution would have been an indication of the "walling-off" process noticed so often in an appendicitis in which no operation has been performed, and the patient temporarily recovers.

I have been unable to find any evidence which points to the existence of characteristic blood conditions in sepsis arising from pelvic or abdominal causes, as distinct from sepsis from foci in other parts of the body, and I think none can be admitted. A felon may produce a leucocytosis alike in kind and degree with that of a septic peritonitis, since the cause of both is the same, while the diseased area involved seems to make little, if any, difference.

Blood examinations, however, are of inestimable value as diagnostic aids in distinguishing between sepsis arising from pelvic and abdominal sources and certain diseases which in other clinical appearances simulate it closely.

Leucocytosis, which is always present in sepsis (except in those severe infections which result fatally within a few hours), is absent in intestinal obstruction (when not cancerous), cystitis, endometritis, tuberculosis (when uncomplicated), typhoid fever, and malaria. Malignant disease is hardly to be confounded with sepsis; but if the question arises, certain morbid changes in the red cells, principally of necrobiotic character, are almost always found in the former, while such changes are rarely, if ever, noted in sepsis, however protracted the case.

The question may arise between a catarrhal and a suppurative appendicitis, in which a blood count, in the opinion of some competent observers, is of diagnostic value.

In a true inflammatory condition about the appendix leucocytosis is almost always present, while in a catarrhal appendicitis leucocytosis may be very slight or absent altogether. I have had little experience in blood examinations for the determination of diagnosis between these two conditions.

A study of the blood will also aid greatly in the prognosis of septic disease. As an indication for operative interference surgeons are more and more availing themselves of its aid; and with the establishment of a clearer comprehension of the causes of leucocytosis and the origin and destiny of the various elements, both normal and pathological, in the blood, a new light will, no doubt, be thrown upon the diseases under discussion, as upon many others which lie much farther within the realm of speculation.

I desire, in conclusion, to acknowledge the assistance which has been given me in the preparation of this paper by Dr. Charles E. Hooker, particularly in the clinical aid which he has rendered me in gathered data. I also take this occasion to thank Drs. Osler, Dock, Loomis, Cabot, and Herrick, for special information on this subject generously furnished me.

May 26, 1898.

THE SERVICEABILITY OF THE ALEXANDER OPERATION IN ASEPTIC ADHERENT RETROVERSIONS OF THE UTERUS, WHEN COMBINED WITH LIBERATION OF IT AND RESECTION AND SUSPENSION OR REMOVAL OF ADNEXA THROUGH THE DILATED INTERNAL INGUINAL RING.

By A. GOLDSPOHN, M.D.,

CHICAGO, ILL.,

PROFESSOR OF GYNÆCOLOGY, POST-GRADUATE MEDICAL SCHOOL; SENIOR GYNÆCOLOGIST TO THE GERMAN HOSPITAL, AND ATTENDING GYNÆCOLOGIST TO THE POST-GRADUATE AND CHARITY HOSPITALS.

Retroversion or retroversio-flexion of the uterus is shown by Ruehl [1] and others to be present in twenty per cent. of all gynæcological cases. It constitutes the most frequent and prolific predisposing cause of inflammatory disorders of this kind. The manifest embarrassments to the venous circulation in the organs, arising from their persistent displacement, induce in them trophic changes analogous to those that bring about a varicose ulcer of the leg, so that they lose, to a large extent, the natural and considerable ability of healthy tissues to defend themselves against infection. To this potent pathological entity, furthermore, are added traumata from adjacent organs, to which the more delicate adnexa, that follow the fundus uteri at short range during its descent, are subjected in consequence of the destructive misapplication of intra-abdominal pressure. The palpable every-day evil consequences arising from these backward inclinations of the long uterine axis have been appreciated by the majority of intelligent physicians during the latter half of this century, and they are this day accepted by said majority as common facts, notwithstanding a doubting or protesting minority, some of whom are determined not to see. It is, therefore, not surprising to behold the operative zeal which has seized our ranks during the present decade to cure permanently these minor disorders—thereby freeing women from present minor ailments, but ultimately and chiefly in a prophylactic sense saving them from either constant torment or the loss of their characteristic organs at some future day. And if these laudable efforts had only been more fortunate in their choice of means to this most worthy end, their blessings to women would indeed be great, in emancipating many thousands of them from many more minor and major ailments; and incidentally not a few large and glittering statistics of easy abdominal sections would be checked that are cherished by some who are ready to open the abdomen freely for any and every reason or excuse. But with the kind of surgical measures which have been extensively adopted for these disorders, I fear that this commendable energy has been largely wasted upon an operative furor of doubtful proclivities.

In order to make a choice of normal surgical or mechanical measures for the temporary or permanent correction of the disorders here referred to, and to judge of the merits of methods now in vogue, and of the one to which I respectfully invite attention, we need to proceed from a consideration of certain fundamental general principles, that I think will or at least should find general acceptation as axioms. The principles that guide me are as follows:

1. The highest uterine and exclusively feminine functions of women—those which chiefly give them their power and grace among men, make them objects of true love, and not merely prolong our race, but make them figure prominently by their influence as mothers in all that is good and noble—are those that pertain to reproduction; and no so-called curative means or method whatsoever is permissible for disorders of an inferior grade, as most uterine displace-

ments are, if such means or method does not favor and possibly disturbs these functions.

2. Inasmuch as, in nearly all instances, retroversion or retroflexion of the uterus is only a minor disorder, causing symptoms usually not unbearable, never causing death, and only remotely inviting more serious lesions, no operation is permissible for it that either in itself or through its complications or sequelæ has any perceptible rate of mortality, or that materially disarranges the normal anatomy, or trespasses upon the physiology of the pelvic or abdominal organs.

3. In view of the moderate nature and degree of the disorders mentioned, no operation is advisable that has frequent sequelæ of physical or mental pain or of other subjective disorder, or whose good results are frequently or easily frustrated with or without the supervention of pregnancy or parturition.

Now, in order to be able to judge whether the procedure which I mean to advocate chiefly is superior or not to others that it will largely compete with, we need first to consider the other measures that are already in the field.

Extraperitoneal Vagino-Fixation of the Uterus.—This operation, aiming to create a fibro-fibrous junction at a point high enough up on the body of the uterus to hold it permanently without a supplementary vesico-fixation or shortening of round ligaments, transgresses the stated requirements so seriously that it has already become practically obsolete, except for cases in which pregnancy is impossible. And I doubt whether a procedure which makes the bladder override the fundus uteri so as to kink the Fallopian tubes backward (Mackenrodt[2]), and which may temporarily occlude the ureters by tension and torsion, as I experienced in a case, should be perpetrated on any one for so slight a cause.

The other similar operations in this field, that vie with each other and still practise their deceptive coquetry quite successfully with a large number of operators, are of the same genus, but belong to more innocent species.

They all have two principal characteristics in common: one of these is that their sum and substance consist in the production of unnatural adhesions, or the construction of bands or bridges, so-called artificial ligaments, which either alone or with associated clefts or loopholes have shown themselves proficient generally, when present from other causes, in entangling intestines and omentum; bands which have no capacity to elongate or to grow in proportion with the uterus in pregnancy, or to become involuted with it subsequently, and the removal of which, if they occurred elsewhere and from other causes in the abdomen or pelvis, would probably be deemed necessary by the same operators who now construct them.

The other chief characteristic of these operations is that their own interests as to the perpetuity of every good that they may or are intended to do are in every detail diametrically opposed to the interests of the uterus in gestation and labor (Noble[3]). Take, for instance, ventro-fixation or ventro-suspension. To avoid obstetric difficulties, it should be made at a point as high up on the abdominal wall as possible, as low down on the anterior surface of the uterus as is consistent with a safe result, and—to allow the deeper layers of the uterine wall to slide past the fixed part of its wall when the uterus expands in gestation (Sippel[4])—the sutures in the uterus should be taken as superficially as is allowable. Each of these features is exactly the reverse of what should be done if permanence of the suspension is the aim of the operator. In principle, I have always viewed these operations as surgical misdemeanors, and, as Edebohls says, repugnant to every surgical instinct.

But by their fruits we must know them, and as the issue in this country is with their most prominent representative, namely, ventro-fixation or ventro-suspension, we will give the past and present friends of this operation a hearing. W. A. N. Dorland[5] has collected 179 cases of pregnancy following this operation. "Of this series, in 120 cases, or 67.03 per cent., a normal gestation was noted; in 111 cases, or 62.01 per cent., labor was absolutely normal; and in 68 cases, or 37.98 per cent., there was an absolutely normal condition throughout both gestation and labor. This leaves a total of 111 cases, or 62.01 per cent., in which some abnormality was noted in gestation, in labor, or in both." Thus nearly two-thirds of these cases of pregnancy have abnormalities, at some time in their course, which are traceable to their previous ventral operation. And more than one-third (37.99 per cent.) of the entire number have such abnormalities in labor, which are the more serious ones. Of cases of pregnancy requiring severe operative delivery after this procedure, 11 occurred out of 54, or 20 per cent., in Milaender's[6] collection; 7 out of Nobles' collection of 43 American cases, or 16.25 per cent.; and 18 in Noble's foreign collection of 133 cases, or 13.5 per cent.

The anatomical disorders arising in gestation after this operation, as we see, in from fourteen to twenty per cent. of the cases, are that the expansion of the uterus takes place almost wholly at the expense of the posterior wall, or of those parts which are above and beyond the point of fixation anteriorly. Therefrom necessarily results a displacement of the cervix and external os backward to or beyond the promontory of the sacrum, so as to make it quite inaccessible; while the hypertrophied anterior wall, not being able to expand, is aggregated into a mass resembling a fibroid (Norris[7]), that obstructs the pelvic inlet. Added to these features is the prevailing transverse position of the child, that results because the uterus cannot expand normally in its long direction (Dorland).

Of subjective disturbances during gestation are mentioned, among others, excessive vomiting of pregnancy (J. C. Cameron[8]), interference with the bladder, and many traction pains of such severity as to induce forced recumbency or to require the induction of premature labor. After carefully excluding the disasters occurring in labor after vagino-fixation, I find, without any exhaustive search, the following as sequelæ of ventro-fixation recorded: By Gubaroff,[21] Veldi,[22] Mackenrodt, R. C. Norris, C. P. Noble, Michaelis,[23] Krim,[24] and Guerard,[25] each one case; two by Strassmann;[26] and four instances in three patients by Bidone.[59] Four Cæsarean sections ended in recovery. Two Porro operations were fatal, and the others each required the severest kind of operative aid. But the remaining sponsors of these operations are gradually renouncing the direct or immediate ventro-fixation of Leopold[10] and Czerny,[11] and they claim that by making an indirect or mediate fixation, as by attaching the round ligaments to the abdominal wall after the original method of Olshausen,[12] or fastening them in the abdominal wound (C. Beck[13]), or by constructing one or more suspensory straps to anchor the uterus with some range of motion against the abdominal wall, by means of the urachus, or by a strip of parietal peritoneum (F. H. Martin[14]), or by allowing an exclusively peritoneal parietal fixation to pull out and form one or more bands of uncertain length and duration, with dangerous interspaces between them (Howard Kelly[15])—that by virtue of such an intervening medium they avoid all the evil consequences spoken of. But what they gain in this direction they lose in another, by exposing their patients seriously to the danger of intestinal obstruction, etc. For a view of such a trap for omentum and intestines, I would refer to a good

illustration of a post-operative specimen removed post-mortem and exhibited by Howard Kelly.*

The harvest of ileus, occurring a year or more after ventro-suspension, is only beginning. But I have chanced to notice the following already: Ruehl,[16] Jacobs,[17] Olshausen,[18] and A. L. Smith [19] each publish a case; and Rufus B. Hall [20] says he has dealt with three cases and thinks the operation of ventro-suspension has had its day. Professor Fritsch [26] did a second abdominal section on a woman who could not walk on account of pain in the abdomen. He found the omentum so engaged between the uterus and the bladder, following a suspension after Olshausen's method, that he had to resect much of it to relieve her. Furthermore, we have the stern fact that Fehling's statistics show a mortality of five per cent. for ventro-fixation (Steinthal [27]); and that ventral hernia has occurred after abdominal section, for this purpose as well as for others, more frequently than that. Finally, every one of these procedures is followed by some uncertain rate of recurrence, which, for intraperitoneal vagino-fixation, is thirty per cent., according to Ruehl.

Now, considering all these facts, let us suppose that every patient with a retroversion, etc., was an intelligent physician and was thoroughly familiar with all these serious ultimate conditions liable to supervene; would the majority of them not vote that the cure is worse than the disease? And would any of them accept such an operation for a retroversion without marked disease of the adnexa, as long as any other method, surgical or otherwise, offered any good at all, without so much of evil? They would not! Then what do we practise when we take advantage of our patients' ignorance and intrude upon them surgical measures and risks which they would not choose if they were better informed?

It is not surprising, in view of such considerations, that a large number, more especially of the younger generation of gynæcologists, who care more for the good they do for women than for ease and convenience to themselves in operating, and who have ambition enough left to overcome some difficulties in technique—have paused, have thought, and then have begun to deal with the round ligaments of the uterus in correcting the backward deviations of its long axis. It is a wonder that not more of them have done so. For here are natural muscular structures, that are always present, that are nearly always sufficiently strong for our purpose, that as a part and parcel of the uterus will keep pace with it in the physiological hypertrophy and involution incident to pregnancy, and that we may make use of in any rational manner for the end in view—no matter what, if anything, was their function previously—without producing any detrimental change of anatomy and without disturbing the function of any organ.

The round ligaments may be approached by three routes: (1) By anterior median vaginal cœliotomy; (2) by median ventral cœliotomy; and (3) by way of the inguinal canals—the last route giving preeminently the best results in all cases in which it can rationally be made to serve.

But before we make our choice here, we must first consider what are all the objects that we need to accomplish. To liberate the uterus, when necessary, and to secure it in normal position, are only half of our duty in many instances of retroversion or retroflexion of it. The other half of our obligation is to extend the same service to its appendages, the ovaries in particular, as well. G. E. Shoemaker says: "In many cases these [the symptoms] are due to displacement of the ovary secondary to the retroversion." The welfare of the ovaries demands that they be supported out of harm's way, laterally against the walls of the true pelvis a little beneath its brim, where that tremendous force—intra-abdominal pressure—will be visited upon them more in a centrifugal (supporting) than in a downward (displacing) direction.*

An ovary that has been displaced so that it approximates the median line of the pelvic cavity, practically always lies upon a lower level also than it should normally occupy. In consequence of this inward and downward displacement, it becomes subject to two potent pathological factors: (1) Partial venous stasis and altered trophic conditions, due to torsion and traction upon veins in its supports; and (2) traumata between the variably filled rectum posteriorly and the uterus anteriorly, especially when the latter is retroverted.

Owing to their more unyielding attachment to the fundus uteri by means of the ovarian ligament, the ovaries have usually lost their normal sheltered location, more or less, when the fundus of the uterus passes from an upper and anterior to a posterior and downward situation. In many instances a thorough restoration of the uterus to normal position—especially when this is done by shortening the round ligaments—will likewise restore a physiological situation for the ovaries also, but in others it will not. It then becomes necessary to shorten the lateral suspensory (spermatic) ligament of the ovary, most frequently of the left side, by stitching a loop in it. This, however, requires an access to the lateral wall of the pelvis, such as can be obtained through a median ventral incision, or through the dilated internal inguinal ring, which is directly in front of the spermatic ligament, but not at all by way of the vagina. The vaginal route, therefore, is serviceable in case we intend to remove the ovaries; but when conservative work on them is contemplated, and their location should be primarily cared for, we can only increase their descensus (Sänger[32]) by drawing them downward and into the narrow median vaginal opening; but we can never benefit it.

Again, the shortening of round ligaments by way of the vagina is an intra-abdominal one, and, like the same thing when done in ventral cœliotomy, it can never equal the results of a thorough Alexander in stability. This fact is appreciated by Kellog,[28] Edebohls,[29] R. Abbe,[30] and F. W. Johnson,[31] to such a degree that they will shorten the round ligaments by the Alexander method even after they have opened the abdomen by a ventral incision for some other purpose. The reason for this is that intra-abdominally the central, stronger portion of the round ligament is shortened by being looped upon itself, or by being stitched to the front side of the uterus (Dudley) or to its fellow of the opposite side; and all this work is made dependent upon sutures that are in danger of cutting out too soon on the one hand, and of cutting off the circulation of the ligament on the other; while, finally, the weakest point of this part of the ligament, *i.e.*, where it enters the abdominal wall, is just as weak as before. On the other hand, by the Alexander method, if precisely followed, the outer, tapering, weaker half of the ligament is eliminated, and the strong central portion alone is made to serve, without loops or dependence upon sutures or adhesions, and in a somewhat straighter course forward than it previously followed. Nevertheless, I frequently shorten the round ligaments intra-abdominally, when I do ventral cœliotomy for grave lesions that this operation alone can really cope with; as for probable or actual septic conditions, or for relief of the most extreme forms of fixation or in-

* Amer. Jour. Med. Sciences, 1896, December, p. 645, fig. 12. Also see "Operative Gynæcology," vol. ii., by Howard Kelly, p. 150, fig. 342.

* See "The Fate of Ovaries in Connection with Retroversion and Retroflexion of the Uterus," by A. Goldspohn, M.D., American Journal of Obstetrics, vol. xxxvi., No. 4. 1897.

carceration of pelvic organs from severe septic processes that may still continue or may have died out, and nearly always after removal of the appendages of one or both sides. At the same time, invariably, also, the lateral suspensory ligament of any ovary that remains is shortened if necessary.

Therefore all anatomical and mechanical conditions, as far as retention of the retroverted uterus and the associated descensus of its adnexa are concerned, point to shortening of the round ligaments by way of the inguinal canals as the normal procedure, whenever the conditions which are essential to its success are present or can be secured by preparatory treatment or by harmless adjunct surgical procedures.

So far, we have but made deductions from unshakable anatomical facts on which the Alexander operation stands. Now what does clinical experience testify for or against it?

1. Mortality practically *nil*. A number of operators have performed it more than a hundred times without any deaths at all chargeable to the operation itself, aside from the narcosis. F. W. Johnson collected 637 cases by nine different operators, with 2 deaths, years ago in the experimental stage of the operation. Kellog says he has performed it in 591 cases, without a death and with no grave symptoms. I have performed the operation over a hundred and twenty-five times certainly, without any death due to the operation. One patient, who should never have been anæsthetized, died on account of marked diabetes mellitus and a prolonged ether anæsthesia for a series of operations, owing to a most unfortunate mistake: *i.e.*, the resident assistant received the urine of another patient for examination and reported upon that. Among foreign surgeons there seems to be no death at all recorded as the result of the operation.

2. It favors conception, does not interfere with gestation or labor, and is rarely followed by a recurrence of the displacement. Stocker[33] observed 21 married women out of a total number of 37 operated upon by the Alexander method. Ten of the 21 married patients gave birth to 13 children at term without unusual complications; and only 2 of the 10 afterward had a recurrence of displacement. A. L. Smith, in 42 total cases (married and unmarried), had 3 primary failures and 3 normal pregnancies. Küstner,[34] in 71 total cases, records 5 pregnancies and no recurrences. Edebohls[35] reports 12 pregnancies in 110 cases after the Alexander operation. Two of these aborted, and one was lost from observation at the seventh month of gestation. Nine terminated safely in normal delivery. And F. W. Johnson has collected 45 cases in which pregnancy took place after the Alexander operation, with only one certain relapse of displacement. There is no recorded case of difficulty in labor due to this operation, and all that is noted during gestation is slight traction pain in the region of the round ligaments during the last months of pregnancy.

It is the unanimous and outspoken opinion of all operators who really have any extended experience with this operation that it is the most nearly ideal procedure for the purpose that we have, because we are dealing with normal anatomical structures in a physiological way; that it can do no harm and endangers nothing, not even hernia, when properly performed; any one can do it who really understands and can execute the Bassini hernia operation correctly.

The requirements for success with the Alexander operation are: 1. A complete and exact diagnosis as to the condition of the uterus and appendages, namely, the location, size, consistence, tenderness, and mobility of each organ, as far as possible, obtained by repeated careful bimanual palpation after thorough emptying of the bladder and intestinal canal, in order to determine not merely their anatomical bearings, but also the more important question whether septic elements, that probably gave rise to the infiltrations and fixations, still exist in the organs or have died out. To exceptional cases in which this point is in doubt, it is well to give the benefit of one or two weeks of recumbency with derivative treatment as a preliminary test. When any very acute tenderness then remains in any portion of the adnexa that is at the same time fixed by adhesions or walled over with the remnants of a former inflammatory exudate, it is more probable that the infective elements have not yet died out, but still remain in variable degrees of activity. In such cases the superior advantages for curing the retroversion, etc., by shortening the round ligaments *via* the inguinal canals, must be relinquished, because a more generous access—one that admits of both sight and a greater scope for palpation—is necessary in order to cope successfully with the conditions when the parts still harbor lingering infectious substances, and also for some few cases of severe adhesions alone with absolute immobility of the uterus. For such cases median ventral or anterior vaginal cœliotomy must be chosen with intra-abdominal shortening of the round ligaments by either route, with the option of making a vagino-fixation of the round ligaments in case of the latter. But this narrow and necessarily limited median vaginal entrance should not be chosen in cases in which, not extirpation, but conservative work upon the appendages is contemplated, such as freeing them from adhesions, resecting an ovary, or restoring the permeability of a tube; because then, quite generally, suspension also of the parts so treated, by shortening the lateral suspensory (spermatic) ligament of the ovary and the ampulla of the tube, becomes a duty almost equal to the correction of the uterine displacement by shortening the round ligaments. And this work upon the lateral wall of the pelvis cannot be done by way of any vaginal approach, which, when dealing with ovaries, induces their descensus (Sänger) but can never correct it.

The second and chief requirement that is an absolutely necessary condition for the success of the Alexander operation is mobility of the uterus and its appendages by securing freedom from adhesions or from marked inflammatory infiltrations of their ligamentous supports or their peritoneal investments.

The uterus must be brought into thorough anteversion and must no longer be displaced from that position by any fixation or force other than gravity. But the very large category of backward deviations of the fundus uteri that present such complications after active sepsis has disappeared are redeemable to perfect eligibility for treatment by this, the most innocent, most natural, and most efficient method of cure for this disorder, by one or more of the following preliminary or preparatory methods of treatment:

1. Bimanual (vagino-abdominal) massage. This is of chief service in reducing cicatricial contraction or inflammatory infiltrations in the ligamentous structures and peritoneal investment of the organs.

2. Redressement forcé in narcosis (method of B. S. Schultze). By this method we can succeed fairly well in liberating the uterus (not so well the appendages) from surfaces that are themselves relatively fixed or stationary, like the posterior wall of Douglas' cul-de-sac; but, like massage, it often fails to sever the adhesions of either uterus or ovaries to movable objects like intestines or omentum, so that these methods require to be supplemented by intraperitoneal digital palpation very generally.

3. Liberating the organs, immediately preceding the Alexander operation, with one or two fingers introduced into Douglas' cul-de-sac by way of the vagina through a sufficient incision posterior to the uterus. So much can readily be done by this approach, but

the more complete ideal work of resecting cystic ovaries, opening occluded tubes, and finally securing these delicate organs in their normal position, cannot be attempted by it.

These considerations, worked out in the course of a generous experience with the Alexander operation and its good clinical results, have led me to introduce

4. The most serviceable of all preparatory or adjunct methods to it, viz., introducing a finger, or two if needed, through the dilated internal inguinal ring of one or both sides successively, when the round ligament has been drawn out. Except in very corpulent women, the entire posterior surface of the uterus and the tube and ovary of the corresponding side can be traced and separated out of adhesions very intelligently, usually by means of an index finger introduced through this opening, simply dilated and not incised. But to liberate the organ successfully with the finger thus introduced it is sometimes necessary to steady the uterus by two fingers of the other hand in the vagina and a volsellum forceps caught upon the anterior lip of the cervix and held by the ring and little finger of that hand. In a few cases of marked adhesions in rather corpulent women, after dilating and curetting the uterus, I have inserted into it a thick blunt (size, English No. 14 to 16) sound of a uniform curve throughout, to correspond to about one-fourth of a circle of a diameter of forty-five centimetres—such a curve being necessary to elevate the fundus of the uterus and, at the same time, avoid making vicious traction upon the sacro-uterine folds or ligaments, elongation of which would detract materially from the good results of the Alexander operation. When the uterus is thus merely prevented from dodging the finger introduced into the abdomen through the inguinal wound, that finger can not only free the posterior surface of the uterus from all adhesions to fixed or movable objects, but it can trace the tube and ovary, free them, and bring both up against the abdominal wall beneath the dilated internal inguinal ring, in which some part of the tube is readily made to appear. It can then be caught by its outer coat with a forceps introduced either alone or alongside of the guiding finger, as the case may require, and can be drawn out, and the ovary follows closely after the ampulla of the tube. Again, if the ovary is the more accessible one of the two, I introduce one blade of a disjointed pedicle forceps with the loop in the handle foremost; then alongside of this I pass an index finger, which guides the ovary into the loop (like a tonsil into a tonsillotome), in which it is drawn out with the assistance of the finger, and then the tube follows. Being delivered out of the opening, which was merely stretched and not cut, they do not tend to slip back very markedly and are safely prevented from doing so by a forceps caught usually on the firm utero-ovarian ligament. In lean subjects the parts are kept from contact with the skin by an intervening layer of gauze, and in fat and corpulent patients the skin incision is made long enough to allow the skin and fat to be retracted, so as to provide a sufficient free area upon the aponeurosis of the external oblique muscle for the parts to rest upon while they are being treated. Then salpingostomy, resection of the ovary, or removal of both tube and ovary can be done very satisfactorily. In many of these cases the ovary can be drawn not merely out of the inguinal ring, but also to some distance in advance of it, thus showing that its ligaments are relaxed and will allow this tender organ to drop proportionally far in the opposite direction down into the small pelvis, so as to suffer the consequences of descensus even when the fundus uteri is in normal position. In these cases I shorten the lateral suspensory (spermatic) ligament of the ovary, by passing a round, curved needle and fine silk through the edge of this ligament at a point as low down in the wound as I can possibly reach by depressing the adjacent abdominal wall, and then passing it midway through the ligamentous connection between the ostium of the tube and the ovary (fimbria ovarica) and uniting these two points, thus making a loop in the spermatic ligament, so that the ovary, when returned, will lie out of harm's way upon the lateral wall of the true pelvis a little beneath its brim, where it belongs.

The serviceability of this inguinal-ring route was impressed upon me on September 18, 1893, when I was for the first time perplexed by not being able to find one of the round ligaments in a living subject. I made an entrance to the abdomen by deepening the inguinal wound, and traced the ligament from the uterus within outward. Incidentally the tube and ovary were discovered to be badly diseased and were taken out. A good cure anatomically and subjectively was obtained, and the patient's serious mental derangement, which had prevented a careful examination and exact diagnosis, disappeared entirely soon after the operation. Since then I have made a practice of introducing a finger and examining the adnexa very generally in connection with the operation upon the ligaments, which can really never be duly drawn out and shortened sufficiently without opening of the peritoneal cavity. But of the practical importance of opening occluded tubes, destroying cystic follicles in ovaries, or removing diseased parts from them, or of securing them in an approximately normal position, I was not convinced until within more recent years, when clinical experience, chiefly with patients after the Alexander and other intrapelvic operations, forced me to accept it as a general principle that in cases of displacement of the uterus any operation for this alone is a fulfilment of little more than half of our duty; that nearly an equal obligation remains for similar prophylactic treatment of the adnexa in a large percentage of cases.

From January 1, 1897, to July 15, 1898, I performed the Alexander operation upon 40 patients; 12 times with diagnostic palpation only, usually of each tube and ovary, through the slightly dilated internal inguinal ring, but without drawing them out into the wound. In 14 cases one ovary was resected. In 2 cases both ovaries were resected. In 8 cases one ovary was removed with the corresponding tube. In 4 cases the tube and ovary of one side were removed and the ovary of the opposite side was resected. In 15 out of the 40 cases, one ovary and the associated abdominal end of the tube were suspended, by shortening the inner edge of the spermatic ligament in the manner described, usually after resection of the ovary or salpingostomy performed upon the occluded end of the tube.

I have been engaged in extending the indications for the Alexander operation beyond the narrow limits of freely movable displacements, and in perfecting its results by means of these benign adjunct procedures upon the adnexa through the same incisions, for nearly five years, as stated: and the uniform good results of these combined procedures are now becoming sufficiently numerous and mature to establish my conviction in their favor; and it is not shaken in the least by all the arguments of opponents, which savor strongly of theoretical construction and assumption, but never of mature experience. And I am glad to notice that during the last several years also two other operators—gynæcologists of the first rank—have likewise independently espoused the dilated internal inguinal ring for similar adjunct work in shortening the round ligaments. G. M. Edebohls[26] says he has liberated the adherent retroverted uterus and appendages by one or two fingers introduced through this opening. Prof. H. Fritsch,[27] during his first year's experience

with this operation, incidentally cured an inguinal hernia in two cases, in one of which he also extirpated a tuberculous tube through the same opening. He says: "If the results are lasting, this is undoubtedly the best, least dangerous, and most correct method of operative cure of retroversion."

Contraindications. — 1. Although the Alexander operation, so extended and improved, is competent to deal with the great majority of movable and adherent retrodeviations of the fundus uteri variously complicated with degenerate conditions, disease, and fixations in the adnexa, which have resulted from previously active septic conditions or from persistent arterial or venous hyperæmia, still it is not intended nor is it competent to cope with either every movable or every fixed retroversion or descensus of the uterus. Its jurisdiction is to shorten the round ligaments of the uterus alone, by the most innocent, rational, and effective method, and to impart to them an important function that either they have lost or may never have possessed —it matters not which is the case. But it does not restore new or lost functions to the other principal ligamentary supports of the uterus. Therefore it cannot cure in those instances of uterine displacement in which not the round ligaments only, but either the sacro-uterine or the broad ligaments or both are also extremely elongated. Practically this means that it must not be chosen (*a*) for actual descensus (prolapse) of the uterus of more than the first degree, or (*b*) for cases of marked elongation of the sacro-uterine folds without descensus proper, as when the fundus lies retroverted and the cervix lies against the anterior vaginal wall down near the urethra.

The function of the round ligaments, in erect posture of the body, is to make occasional forward traction upon the body of the uterus in an approximately horizontal direction. A salutary sustaining impact of intra-abdominal pressure upon the posterior surface of the uterus is thereby invited, which, as the predominating force, then supports the organ in anteversion. This play of forces is, however, secured only when the uterus as a whole has not descended too far in the pelvic canal and when its lower pole, the cervix, is normally retracted toward the sacral cavity. In the absence of these essential conditions, the shortening of the round ligaments would merely be a suspension of the uterus against the pubic arch by means of the round ligaments (then drawing upward), which would be grossly irrational and ineffective. Shortening the sacro-uterine ligaments or folds, if possible, would be far more rational and auspicious in such cases.

2. When the body of the uterus is extremely large and heavy, either from inflammatory processes or from fibroids, and is at the same time markedly and stiffly retroflexed, the round ligaments should not be appealed to to secure it in adequate anteversion, because the centre of gravity in such cases falls from a point too far posterior to a line joining the points of origin of the round ligaments upon the uterus. Fortunately the cases of this kind and likewise those of the preceding category that are ineligible even for the improved Alexander operation, on account of too great descensus uteri, occur mostly in women who are beyond the period of possible or probable childbearing, and may therefore be safely and efficiently treated by means of a direct or a mediate ventro-fixation supplemented by thorough restoration of the pelvic floor.

Technique.—This is a delicate subject in the performance of any simple Alexander operation. It has been the chief barrier to the adoption of this procedure, in its simplest form, by numerous operators. An anatomically correct and carefully executed technique is of vital importance, particularly when so much intraperitoneal work is done through the same openings, if not merely primary, but also permanent, good anatomical and subjective results are to be quite uniformly obtained without the supervention of hernia or other evil sequelæ. That this is possible when the following fundamental principles are adhered to in this procedure my results have demonstrated, which are corroborated by the allied anatomical researches of O. Büttner,[58] of Geneva:

1. In making the wound, all cutting must be limited to skin, fat, a few circular fibres at the outer angle of the external inguinal ring, and the initial opening into the peritoneum, and all the aponeurotic and muscular—really supporting—structures be cleft solely by blunt instruments, so that they will fall together again when the retractors are removed.

2. The portion of each round ligament which lies within the broad ligament must be thoroughly drawn out—never less than ten centimetres—by always opening the peritoneum and cutting or stripping it down in such a manner as to leave the strip of peritoneum, by means of which this structure is usually united with one side of the round ligament, in contact with the latter to reinforce it and make it equal to its task, even when not well developed.

3. Closure of the wound must be effected by careful individual coaptation of the structures in each of at least four layers with absorbable sutures of sufficient resistance; and in this the principle of the Bassini hernia operation must be thoroughly adopted.

4. Each shortened round ligament must be anchored against the posterior surface of Poupart's ligament, an unyielding object, and any serious embarrassment of its circulation must be guarded against by grasping it, never alone, but always together with a roll of muscle, in all the sutures, which must be so placed as likewise to effect a reconstruction or reinforcement of the posterior wall of the inguinal canal. Thorough work, as well as good and permanent results, demand that the inguinal canal be, as a rule, entirely laid open. It is harmless to do this if all cutting be avoided in bearing structures, and if they be properly reunited. And in view of the important objects achieved by this improved Alexander operation, the objections to any scars are silly prudery, such as may be indulged in possibly by those who make merchandise of their bodies.

An incision, five to seven centimetres in length, is made from the pubic spine upward and outward parallel with Poupart's ligament, and one to one and one-half centimetres above it, down to the aponeurosis of the external oblique muscle. After this structure and the margins of the external abdominal ring in it are clearly exposed, the projecting bunch of fat with terminal filaments of the round ligament and the ileo-inguinal nerve are caught in a forceps and drawn upon somewhat, while a few circular fibres at the outer angle of the ring are cut with scissors. The aponeurosis is then split with a blunt instrument far enough to expose the canal and is held apart with retractors. The inguinal canal being now open and the ileo-inguinal nerve in sight, the round ligament can usually be traced from its terminal filaments, in the grasp of the forceps, upward and outward. In exceptional cases, when this does not succeed, a bunch of muscle near the internal abdominal ring is picked up with a blunt hook and drawn upon, while an assistant places a finger against the cervix in the vagina and observes whether a corresponding motion is imparted to the uterus. If not, another grasp of muscle is taken, until the round ligament is included. It is then isolated from the muscle with as little contusion as possible. The web of peritoneum presenting on the outer side of the ligament, when drawn out, is preferably incised with scissors, so that it will present distinct margins for subsequent manipulation. From this opening the cone-like investment of peritoneum is detached from

the ligament on all except its inner or anterior sides, where a firmly united strip of peritoneum is left to reinforce the ligament, which, in the mean time, has been amply drawn out. The opening, if not already large enough, is dilated by spreading the jaws of a pedicle forceps within it, until it admits an index finger, with which the parts within should always be examined. And with this finger they can be thoroughly freed from adhesions, and the tube or ovary can be brought into view beneath the opening, can readily be drawn out, and can be subjected to ideal conservative surgical treatment, as before described, or removed, as indicated.

As the first tier of sutures, the opening in the peritoneum and transversalis fascia is closed by a continuous fine catgut suture, which unites it to the round ligament drawn out *ad maximum*, so that when it naturally recedes somewhat it will tent the peritoneum inward and deflect intra-abdominal pressure. The second tier of sutures is made preferably with a double thread of a medium-sized catgut, and is begun in the lateral angle of the wound at the outside of the formerly dilated internal ring. By this the muscular aperture, which has already collapsed, is now firmly closed by several continuous stitches, the last one being looped under itself without tying. The needle next gathers up a roll of muscle, from one-half to one centimetre in thickness, from that part of the internal oblique and transversalis muscle lying above the opening just closed; it then passes through about the centre of the round ligament, is again well drawn out, and finally takes a sufficient grasp upon the posterior surface of Poupart's ligament at about its middle. When this suture is drawn upon it not only closes the internal ring, but also brings an additional layer of muscle down over it, and closes the outer end of the inguinal canal by bringing this aggregation of muscle down against Poupart's ligament, with the round ligament cushioned between the two. Three or four more such stitches are taken continuously from without inward, in each of which a similar roll of elastic muscle is first gathered up before the needle passes through the round ligament and anchors it flatly against the posterior surface of Poupart's ligament for a distance of three or four centimetres. While each or every second one of these stitches is hitched under itself to prevent it from slipping, the last one is tied in a single-thread knot by passing one of the two threads under the double thread back of the last stitch. This second tier of sutures has accomplished three very important objects: (*a*) firm closure of the inguinal canal throughout; (*b*) secure attachment of the round ligament to an unyielding object; (*c*) guarantee of sufficient circulation in the round ligament, because it is everywhere grasped with a cushion of elastic and very vascular muscle tissue.

In order to make this suturing against the posterior surface of Poupart's ligament possible, its upper edge, which is the lower split edge of the wound in the aponeurosis of the external oblique muscle, has in the mean time been grasped in a pedicle forceps (not too tightly) and turned over outward and downward, thus turning its posterior surface upward. Now, at the finish of the second layer of sutures, these separated edges of this aponeurosis are both liberated respectively from the forceps below and the retractor above, and they fall together; and their union constitutes the third tier of sutures, which is made continuously with a single thread of medium-sized catgut, beginning with closure of the external abdominal ring, in which the round ligament is again grasped and then cut off, and proceeding outward to the end of the cleft in the fascia. At some point in its course, or at the finish, this thread is tied with one of the ends that was left projecting from the knot at the beginning of the previous (second) tier of sutures. In that manner all these three layers now closed become solidly united against each other, even in the lateral portion of the wound.

In closing the skin-and-fat incision, it is difficult to avoid the formation of a dead space below Poupart's ligament, because the proximity of the iliac vessels makes it too dangerous to seize enough of the tissues at the bottom of the wound there. I therefore place a bundle of silkworm gut threads (eight or twelve), seven to eight centimetres long, into the most pendent portion of the bottom of the wound, leaving only one end of it, that has a thread tied about it, to project from the lateral end of the skin wound, which drains out large amounts of serum frequently and secures a primary union more uniformly. The bundle is drawn out painlessly after forty-eight or seventy-two hours. The skin and subcutaneous tissues are united as the fourth layer, by either continuous or interrupted silkworm-gut sutures.

I would respectfully suggest that the operation performed in this manner and embracing the very important intraperitoneal adjuncts, by means of which its usefulness is both multiplied and extended over a new, wider, and more important realm, be called the extended and improved Alexander operation.

Naturally every patient who needs this operation also needs a curettage as the first step. And all parous women, with such a displacement of the uterus, usually require also a cervix operation or a restoration of the pelvic floor, or both, in addition to the operation above described, in order reasonably to fill the indications pertaining to these structures. And, as a final act, hemorrhoids frequently require to be removed. From one to four of these supplementary operations I have performed in every case, in conjunction with the main operation just named and in the same narcosis.

As a detailed inquiry and a medical examination in all the cases have not yet been completed, and because longer time for observation is needed for many of them, a detailed statistical statement of the results is better deferred to a later occasion. But from an examination of about one-half the cases, and from quite a general knowledge of the state of health of most of the rest, I can assure my colleagues that recurrences of displacement, with and without pregnancy, have not occurred in more than two per cent.; that disorders of gestation and complications in labor have not arisen from the operation; that while two complete and three incomplete inguinal herniæ and two small femoral herniæ have been incidentally cured (the latter being approached by drawing the skin and subcutaneous tissues on the lower side of the wound down far enough), no hernia has followed the operation; that the annoyances to patient and doctor from persistent or recurring symptoms of disease in the adnexa have been less frequent than in other cases in which similar conservative work was done by cœliotomy; and that the degree of general satisfaction derived from cases treated in this manner constrains me to invite for this operation an extended trial and observation.

NOTES ON THE THERAPEUTIC USES OF THE SUPRARENAL GLAND.[1]

By W. H. BATES, M.D.,

NEW YORK.

In 1894, after a series of experiments on the ductless glands, I began to use the aqueous extract of the suprarenal in diseases of the eye. Since that time I have used it continually, with ever-increasing gratification; and after four years I feel that I have thoroughly defined its advantages and limitations in diseases of the eye, ear, nose, and throat. With diseases of these organs my personal observation ends; but I reasoned that an agent so powerful (the patients call it "wonderful") in inflammations of mucous membranes of these special organs would have a similar action in inflammations of other mucous membranes. Also from a study of its physiological action and a few cases in which evident symptoms of heart disease were relieved by its instillation into the eye, I was convinced that it was an ideal heart tonic. As I am unable to follow it up in general diseases, I wish some other member of the society would study it clinically and present this valuable agent to the medical world. This is why I read before the society these incomplete arguments and scattered observations.

In the *New York Medical Journal*, March 16, 1896, I published the preparation in detail. It is essential to remember that the active principle of the gland is incompatible with preservatives and that it is weakened by heat; consequently it must be freshly prepared when needed. This can be done without much trouble. I mix ten grains of the dried gland with two drachms of water, and filter. The filtrate is a one-per-cent. solution of the extract.

The aqueous extract of the suprarenal gland is the most powerful astringent known. When a drop of a one-per-cent. solution is instilled into the eye, the conjunctiva of the globe and lids is whitened in from forty seconds to two minutes. This original observation was published in the *New York Medical Journal*, May 16, 1896, and was soon confirmed by L. Dor,[1] Lucien Howe,[2] and by many others. The extract has been used (more than five thousand times) in all forms of inflammation of the eye, whether traumatic, infectious, or from constitutional diseases—as rheumatism, syphilis, or tuberculosis; it always produced a whitening of the eye. The pupil is not contracted or dilated by it. A tolerance is not established by its use. It has no antiseptic or anæsthetic properties. The relief of pain and the quick cures often made are due entirely to its wonderful astringent property.

The extract will whiten the granulations which are found in cases of suppurative otitis. In dry catarrh the extract is often valuable to relieve congestion. I could report twenty-five cases of deafness in which the hearing was decidedly improved by it after the usual measures had failed. Cases of tinnitus have been permanently relieved by the suprarenal. In ankylosis of the stapes the extract was not beneficial, which fact and others suggest that the indication for its use is in inflammation or congestion. It is valuable in differential diagnosis and is a great help in prognosis, as well as in therapeutics. For example: If the suprarenal improves the hearing we have a case which is inflammatory, the prognosis is favorable, and the treatment should be to relieve congestion.

The extract will lessen the congestion of the turbinated bodies immediately and open the nose, after cocaine and other astringents fail.

I have used the extract in two hundred eye operations, and noted that it lessens the congestion of an inflamed eye sufficiently to permit cocaine anæsthesia. As cocaine and the extract are incompatible, they should be used alternately. I have reported cases of inflammatory glaucoma, strabismus, dacryocystitis, and other affections in which the operation was made painless only after the extract was used with the cocaine. This valuable property of the gland has been confirmed by L. Dor, Darier, and others.

Dr. Joseph A. Mullen[3] has reported seven nasal operations in which the extract prevented hemorrhage. He applied it by cataphoresis.

In dentistry its use is indicated. I know of one case, in which cocaine produced no anæsthesia of a hypersensitive nerve until the extract and cocaine were used alternately.

Strictures.—When the nasal duct is closed by swelling of the lining mucous membrane, the extract syringed into the punctum lessens the congestion and swelling by its astringent action and the duct becomes open immediately, so that water may be made to pass through it freely. The extract succeeds when cocaine fails. Cases of stricture caused by bone or connective tissue are naturally not affected by an astringent, and require operation. Many cases of stricture of the nasal duct have been cured by treatment with the extract, which, without it, would have required an operation for relief.

This successful employment for stricture of the nasal duct suggests its use in strictures of the urethra, œsophagus, pylorus, etc. Dr. J. M. Otto used it in a case of urethral stricture; it relieved the congestion of the parts sufficiently to permit the introduction of a larger sound than could have been introduced without it. An internal urethrotomy was painless and without hemorrhage.

In Skin Diseases.—Velich[1] found that the extract produces local anæmia when applied to the skin, not only when there is a lesion of continuity, but also when the cuticle is unbroken. He whitened the inflamed skin of a burn, and believed that he prevented vesiculation. The extract has been used to whiten an eczematous patch. It is also recommended in smallpox, to prevent vesiculation, with the object of avoiding disfigurement of the face. In cases of intertrigo Velich has brought about the disappearance of the hyperæmia by the use of compresses imbued with the extract. In sarcoma in rats he produced anæmia of the diseased tissue.

Pernicious Anæmia.—Dr. Douglas Stanley[2] found that in one case the freshly prepared aqueous extract produced a marked increase in the number of red blood corpuscles.

Addison's Disease.—Osler, in his "Practice of Medicine," asserts his belief that the suprarenal extract is valuable in this disease. The literature on this subject is very extensive.

Heart.—The physiological properties of the extract suggest its usefulness in organic diseases of the heart of a varied character. The extract has been demonstrated by Oliver and Schäfer[3] to be a tonic of the heart muscle. The tension can be increased enormously by intravenous injection, less markedly by its subcutaneous use, and its action is very uncertain when administered by the mouth. The suprarenal is much more powerful than digitalis or ergot. The following cases are suggestive:

Case I.—A woman, aged eighty-seven, was treated by Dr. James Watkins for a complication of diseases. He found the pulse weak, irregular, and intermitting every second beat. June 1, 1895, the extract was used in the eyes to relieve an inflammation. The solution was instilled every two hours during the day. The patient called attention to the fact that her pulse was better, and it was noted that it was strong, regular, and did not intermit. The doctor was convinced that the extract benefited the heart. The extract was used for more than six months, with marked benefit.

Case II.—A married woman, aged nineteen, was seen, January 27, 1897, by Dr. C. J. Mooney. He stated that there was a mitral regurgitant murmur; also a murmur from aortic stenosis. The pulse was 94, high in tension, weak, wiry, and regular. The lips and face of the patient were pale. After a hypodermic injection of five minims of a one-per-cent. solution, in ten minutes the pulse was 82, full, compressible, of medium tension, not wiry, and regular. The lips and face had a decided improvement in color. Dr. Mooney believed that the heart was strengthened by the injection. The skin at the point of the injection was whitened in a space about two inches in diameter. It was painful, tender, and two days later was swollen. The disagreeable local symptoms disappeared in a week.

Case III.—A man, aged fifty-five, was a patient of Dr. J. C. Peterson, who furnished the following notes: There was a mitral and aortic regurgitant murmur. Pulse, 68, wiry. The patient suffered severe pain from angina pectoris, for which he required morphine. The portal circulation was impeded, and there was dropsy of the feet. On February 3, 1897, the patient received a hypodermic injection of five minims of a one-per-cent. solution of the extract. After five minutes the pulse lost the wiry feeling and became more regular and a little slower—64. The peripheral circulation was improved. The most marked effect was made on the angina—the anxious feeling, oppression, and pain were relieved for five hours. Other injections were made, with benefit. The patient did not complain of the local pain of the injections.

Case IV.—A woman, aged twenty-one, was treated by Dr. Warren Schoonover. There was a mitral regurgitant murmur. The patient had also aortic stenosis. The pulse was described by the doctor to be bounding, explosive, dicrotic, and irregular. Digitalin, grain one-sixtieth, administered every four hours, had not relieved the patient. The patient was given ten grains of the powder, to be swallowed with a little water, the quantity to be repeated every four hours. The pulse became regular and the patient's subjective symptoms were relieved for two days. The powdered glands then failed to relieve.

Case V.—A woman, aged forty-three, was treated by Dr. Augustus Milleg for pleuro-pneumonia complicated with organic heart diseases, mitral obstruction. The pulse, 100, was soft and intermitted every fifth beat. The temperature in the beginning was 103.5° F. The crisis developed February 9th, eight days after the onset of the disease, the temperature falling to 97° F. She had the Hippocratic facies, cold extremities, a very weak pulse, and felt that she was dying. She was given a hypodermic of ten minims of a five-per-cent. solution of the extract. In a few minutes the pulse was 120, full, and strong. The extremities became warm and the patient felt exhilarated. She received four daily injections with great benefit. The doctor believed that without the suprarenal extract the patient would have died of heart failure. The injections caused local pain. The patient recovered from the pneumonia.

Exophthalmic Goitre.—Dr. George W. Crary used the extract of the suprarenal capsule in one case.[1] He observed a decided improvement in the action of the heart; also an improvement in the general muscular strength, which is what we should expect from its physiological properties. The goitre had almost entirely disappeared, the tremor was not very marked, and the patient had gained considerably in flesh. The patient took one tablet, representing eight grains of the gland, three times daily.

In my opinion the best way to administer the gland is to place a few drops of the aqueous extract on the tongue.

To recapitulate: As a pure astringent in all inflammations, as a hæmostatic, and as a tonic—I might almost say food—to all muscle fibres, especially the heart, no therapeutic agent has been employed which can compare with the extract of the suprarenal gland.

Etiology of Leucorrhœa.—The causes of leucorrhœa may be divided into two classes—constitutional and local. Constitutional causes are anything that lowers the individual's general vitality, as any acute or chronic diseases, among them being fevers, rheumatism, gout, syphilis, anæmia, and chlorosis. Local causes are vaginitis, simple or specific; endometritis, cervical or corporal; salpingitis, when the products of the inflammation escape into the uterus and from thence out; polypi; fibroids; excessive coitus; ulcerations, simple, specific, and malignant; uterine displacements. When it is, strictly speaking, of inflammatory origin the discharge is constant, though at times it may be much more profuse than at others; but when it is due to a relaxed condition of the mucosa, it is very much increased and often is present only shortly before and a few days after the menstrual flow, or when the patient has been subjected to some unusual physical or mental strain.—Dr. Ralph Waldo, *Post-Graduate*, April.

MYOCLONUS MULTIPLEX MITIOR.

By W. MOSER, M.D.,
BROOKLYN, N. Y.

Definition.—Myoclonus (μῦς, muscle; κλόνος, clonus) signifies a clonic contraction or contractions of a muscle. The term myoclonus multiplex signifies clonic contractions of different muscles of the body, rather than a clonic contraction of one special muscle. I have appended the word "mitior," signifying milder, as is done by writers in epilepsy to distinguish it from "gravior," meaning a more serious or pronounced character of a given affection.

Etiology.—Prolonged mental worry or emotion and excessive venery appeared to act as exciting causes in the few cases under observation. It must be admitted, however, that the real cause or its true pathology is obscure. In one case, that of a man, fear of contracting hydrophobia (after a dog bite) produced the disease. It is not so apt to occur from mental emotion of short duration, as in cases in which the fear or the worry is prolonged.

Symptoms.—Such a patient consults a physician for one symptom more than any other, and the title of this paper explains what that symptom is. He is conscious of twitchings in his muscles. He has seen his index finger or some other finger of his hand moving to and fro, due to alternate contraction and relaxation of the muscle attached to that finger. At another time he may have seen "throbbing" (clonic contraction) of some large muscle, like the biceps or deltoid, or some large muscle in the leg. The large muscles of the back are not infrequently affected. During contractions in the sterno-cleido-mastoid, the head may be drawn slightly to the affected side. The neck, on one side, sometimes feels stiff, owing to contractions of the platysma myoides. The duration and frequency of the contractions are varied, sometimes lasting only a few seconds, while again I have seen them last twenty minutes or more. They may be entirely absent for days, only to recur, now in one muscle, then in another. There is no bilateral symmetry. Only in a few instances have I caused the muscles to contract by tapping them. As a rule, they did not do this. The contractions are not painful.

Diagnosis.—It could be confounded with the convulsive tremor of Friedreich. Here the contractions are "shock-like" in character, they are more symmetrical, and the extremities remain uninvolved. What relation the condition in question bears to paramyoclonus multiplex, I cannot say. It has some resemblance to it, only being of a milder character. The contractions are not so varied in their distribution in paramyoclonus multiplex, in which the extremities are chiefly affected; while in the disease in question the muscles of the neck, back, or abdomen are as frequently affected as those of the extremities. It could not be confounded with progressive muscular atrophy, because the muscles do not atrophy at any time in the disease. The symptoms of hysteria are absent, nor is it improved by suggestion or hypnotism. There is no ataxia, paralysis, or, in fact, any other well-marked symptom referable to the central nervous system. The mind is clear, and the affection must not be confounded with general paresis. It is not "neurasthenia," in which condition twitchings of the muscles may at times occur. The strange feature is that such individuals are, aside from these clonic contractions in the muscles, otherwise mentally and physically sound. Twitchings of the eyelids are not infrequent.

Prognosis is good, although the contractions may extend over a period of months. The electric irritability of the muscles is normal.

Treatment.—Strychnine in small doses, electricity, and salt-water baths may be of service. Massage is to be recommended, since patients themselves have noted that by only slightly rubbing the contracted muscle it at times has become passive.

Progress of Medical Science.

Migraine and Epilepsy.—Rachford (*American Journal of the Medical Sciences*, April) is convinced that the relationship of migraine and epilepsy is one of the facts of medicine and not one of its theories. He believes that he has proven that paraxanthin is a most important factor in true migraine, and that it is also an important factor in the production of one form of toxic epilepsy. He says that migraine, therefore, bears a close etiological relationship only to toxic epilepsy, and possibly only to the form of epilepsy which he has described as paraxanthin epilepsy.

Sulphate of Potassium and Hepatic Cirrhosis.—Lancereaux, having been struck by the absence of drunkenness in the subjects of cirrhosis, has investigated the influence of various alcoholic liquors in the production of cirrhosis. In two hundred and ten cases of cirrhosis examined by him in thirty-five years, sixty-eight of the subjects had drunk wine alone to excess; one hundred and twenty-six, wine in combination with brandy, rum, or absinthe; twelve, wine and beer; and four wine and cider in large quantities. These figures clearly show that, in Paris at any rate, wine, and not alcoholic drinks generally, must be considered the antecedent of cirrhosis. Conversely, in Brittany and Normandy, where little wine but much brandy is drunk, cirrhosis is rare. In Hayti, where a great deal of rum and arrack is consumed, hepatic cirrhosis is unknown. Lancereaux finds that the poisonous body in wine is sulphate of potassium; in Paris plastered wines contain four to six grams of this salt per litre, and three litres per diem was the average quantity taken in the cases he investigated. That sulphate of potassium alone gives rise to cirrhosis he proved by feeding rabbits, guinea-pigs, and dogs with it. After surviving for from six to eighteen months they died, and presented typical venous cirrhosis. The general consensus of opinion expressed by those who have given alcohol experimentally to animals is that it sets up fatty degeneration in liver cells, but does not produce cirrhosis. It appears that there is some body other than alcohol in alcoholic drinks which gives rise to cirrhosis, and this Lancereaux believes, is the salts of potassium, especially the sulphates. Unfortunately, an accurate chemical analysis of the stimulating drinks of various countries and of their adulterations is wanting. But it is not improbable that in Germany and England, where beer gives rise to cirrhosis, this beverage contains sulphate of potassium. If it were not for its familiarity, the term "alcoholic cirrhosis" should be replaced by "drinkers' cirrhosis," inasmuch as there is no reason to incriminate alcohol as a cause. To prevent the occurrence of cirrhosis, the "plastering" of wine ought to be forbidden by law.—*British Medical Journal.*

Treatment of Peritonitis.—As regards the medicinal treatment of peritonitis, one of the most important and at the same time the most difficult objects is to prevent the administration of opium or morphine in any form. I believe this drug to be the frequent cause of death. In all cases of peritonitis, whether local or general, one of the worst features is the passive distention of the intestines with gas which they are unable to contract upon and expel; and I believe that the vomiting, shock, and other fatal symptoms are as much due to this distention as to septic absorption.

The greater the distention the more powerless is the intestine to contract. Thus, then, the utmost trouble should be taken to prevent the distention getting to unmanageable proportions. Such distention is directly encouraged by morphine, for the first effect of this drug is to produce a temporary paralysis of the circular fibres, thus inhibiting peristaltic action. This gives relief from the pain, and the patient sleeps. What is the result? When the patient awakens a few hours later the condition has become infinitely worse. Nature all this time has made no effort to relieve the distention, and gas has accumulated beyond the power of expulsion. It is doubtless the temporary ease thus gained by smothering the pain that has made the administration of morphine so common a practice in the treatment of peritonitis. As a matter of fact, the sleep which the friends think so beneficial is the death warrant. Spasms of pain show that efforts are still being made by the bowels to resist distention and expel the fast-accumulating gas. The cessation of these efforts means that nature has thrown up the contest—a condition of affairs that morphine quickly brings about. I have heard it remarked that "it quiets the nervous system." It certainly does so, only too effectively.—Dr. Harrison Cripps, "Ovariotomy and Abdominal Surgery," p. 214.

The Rôle of Insects in the Transmission of Contagious Diseases.—T. R. Joly relates instances of malignant pustule, Egyptian ophthalmia, and Delhi boil conveyed by flies. He has also found as the result of careful observations that the legs of flies may be covered with staphylococci and many other forms of bacteria. Tubercle is particularly liable to be disseminated by flies; thus they come in contact with sputa and other substances whereby tubercle bacilli discharged from the body of a patient become ingested. The insects then alight on food and deposit the tubercle bacilli, and thus easily contaminate milk, meat, and other substances. The author mentions Yersin as having noticed that the bodies of dead flies collected in his laboratory often contained numbers of the plague bacillus. The influence of various insects, more particularly mosquitoes, in carrying the filaria sanguinis is well known. The mosquito has also been suspected as the agent in the conveyance of malaria, and the writer suggests that the "sleeping-sickness" is due to infection carried by insects. Ordinary inflammatory conditions may be produced by the common flea or bed-bug, though the writer has been unable to find that the latter insect carries tuberculosis infection, as is stated by some observers. The writer goes on to show the importance of warding off flies as far as possible, especially in cases of the diseases mentioned. He suggests a solution of formol as of considerable use for this purpose, and particularly good in cases of pityriasis.—*British Medical Journal.*

Suppuration in the Peritoneal Cavity.—Contrary to what was formerly believed, the peritoneal cavity is a place where suppuration in many cases is less likely to occur after the entrance of micro-organisms than are the cellular or muscular tissues, and many points with regard to the anatomical and physiological characters of the peritoneum come into play in explanation of this fact; to mention one, the peritoneum is a membrane which absorbs fluids with the very greatest rapidity, and in this way deprives bacteria of the necessary pabulum, and brings them into immediate contact with the active cells, either epithelial or plasma cells.—Dr. W. Watson Cheyne, Treves' "System of Surgery," vol. i., p. 85.

Epistaxis.—Bleeding from the nose is a frequent occurrence in interstitial nephritis. It is said to occur at all stages, but mostly at the beginning and the end of the disease. It is also met with in threatened uræmic attacks, on account of the increased arterial tension. Hence the propriety of examining the urine in all cases of recurrent epistaxis, especially in elderly people. Its relation to apoplexy has been frequently discussed. By some it is maintained that it tends to ward off such attacks, and hence may be regarded as beneficial.—*Scottish Medical and Surgical Journal.*

Hæmaturia.—Dr. David Newman (*The Lancet*, July 2d) makes the following statement: "We may classify the diseases of the kidney commonly associated with blood in the urine under the following heads: (1) Traumatic lesions—(*a*) from injury and (*b*) from calculus; (2) passive hyperæmia—(*a*) pressure on the renal veins, (*b*) torsion of the renal veins, and (*c*) reflex spasm of arterioles; (3) inflammatory hyperæmia—(*a*) nephritis, acute and chronic, (*b*) tuberculous disease, and (*c*) cystic degeneration and hydatids; (4) tumors of the kidney.

Hydatid Cysts.—In the removal of hydatid cysts it must be clearly borne in mind that there are two walls—an outer, formed by inflammatory condensation of the tissues and the tissue in which the tumor is growing, and an inner, the lining membrane forming the true cyst wall. This latter can be pealed off, but the outer should on no account be touched.—Harrison Cripps.

Cholelithiasis.—Dr. A. H. Cordier, in an article entitled "Some Pathological and Clinical Phases of Gall Stones" (*The Journal of the American Medical Association*), concludes as follows: (1) Cholelithiasis is of frequent occurrence and usually gives rise to symptoms either severe or obscure. (2) Cholesterin as a gall-stone-producing agent must be present in an abnormal quantity. (3) Cholesterin is in a great measure a product resulting from the destruction and disintegration of the epithelium of the biliary ducts and gall bladder. (4) Bilirubin-calcium, an insoluble compound resulting from the union of bilirubin and the lime salts, is the nucleus of most of the stones formed in the gall bladder. (5) Jaundice, ptomain poisoning, and suppuration are late symptoms of cholelithiasis. (6) Dyspeptic symptoms, swarthy skin, uneasiness in the region of the gall bladder (congestion of liver), and loss of weight are some of the remote and local symptoms of the presence of gall stones. (7) Inflammatory diseases of the duodenum and bile passages are the most direct causative factors in the production of gall stones. (8) The surgery of these cases is especially difficult, and the inexperienced should not undertake it. (9) A ball-valve stone usually continues to give rise to symptoms until removed by surgical means. (10) Stones in the gall bladder, producing septic symptoms, should be removed.

The Widal Test for the Diagnosis of Typhoid Fever.—Dr. W. H. Welch, of Baltimore, in a paper read before the American Medical Association, summarized as follows: (1) Experience has demonstrated that the method of serum diagnosis of typhoid fever is of great practical value. (2) The alteration of the blood on which this method is based is a specific effect of infection or intoxication with the typhoid bacillus. (3) The microscopical serum test is to be preferred to the macroscopical methods. (4) Quantitative determinations, relating especially to the culture, the time limits, and the dilution of the serum, are of importance, and, at least in doubtful cases, should not be neglected. (5) As the reaction may be delayed or occasionally absent, a negative result of the test does not exclude the diagnosis of typhoid fever. The later in the course of the disease the test is applied, and the oftener the examinations are repeated at

intervals, the less is the probability of the existence of typhoid fever, if the reaction is not manifest. (6) The persistence of the reaction, sometimes for years after recovery from typhoid fever, is to be borne in mind in interpreting a reaction in febrile conditions. The appearance of the reaction and its increase during the period of observation speak for fresh typhoid infection. (7) The danger of mistakes from positive reactions in non-typhoid cases can be guarded against in nearly all instances. (8) Provision should be made, especially by the establishment and support of municipal or State laboratories, to render generally available to practitioners the serum method of diagnosis, as well as other bacteriological procedures of similar practical value.

The Galvanic Current for the Treatment of Pterygium.—Dr. Horace M. Starkey (*Journal of the American Medical Association*, September 17th) says the cases which seem to be suitable for electrolysis are those with small pterygia, not encroaching much upon the cornea, and particularly those in which there is considerable enlargement of blood-vessels. The way in which the electricity acts upon the tissues is as follows: (1) It coagulates the blood in the vessels, thus stopping the blood current and causing the vessels to disappear. (2) It produces a mild adhesive inflammation of the subconjunctival tissues, thus forming a firm cicatrix between the conjunctiva and the sclera, so that the gliding of the former over the latter is prevented, and (3) it destroys micro-organisms in the tissues, so that, if the claims advanced by certain investigators that micro-organisms are the cause of this disease should prove to be well founded, this treatment would still be rational. The advantages of this method are: First, it avoids any loss of tissue; second, it is painless; third, it does not incapacitate the patient; fourth, it stops the progress of pterygia seen in the early stages. With these advantages is coupled the fact that it seems quite as free from recurrences as any other method. It is not advised, except as a palliative, in broad fleshy pterygia or in those encroaching much upon the cornea.

Lead Poisoning.—Dr. Arthur Whitelegge, chief inspector of factories and workshops, makes the following report of the results of lead poisoning (*British Medical Journal*, July 23d): "As it occurs among workers in lead the symptoms of plumbism may be acute or chronic, and in the chronic cases there occur from time to time acute exacerbations. The acute poisoning is seen at its worst in young persons, and especially in girls, who have recently commenced to work in the factories. Sometimes they suffer from severe colic, with constipation, lasting a few days; or they may have violent diarrhœa and other gastro-intestinal symptoms of severe irritant poisoning, often leading to a fatal termination in a week or two. Or they may suffer from acute anæmia followed by fits and delirium, often by a rapidly fatal issue. Among the symptoms of chronic poisoning are the well-known anæmia, blue line on the gums, colic, paralysis and cramps of muscles, the so-called 'encephalopathia saturnina,' gout, cirrhosis of the kidneys, and affections of the organs of reproduction. In a series of thirteen hundred and ninety cases colic occurred in eighty-eight per cent., paralysis in seven per cent., and encephalopathy in five per cent. The paralysis is usually of the forearm type, giving the characteristic double wristdrop; sometimes, however, it is of the upper-arm type, affecting the deltoid, biceps, and supinator longus; sometimes of the ordinary (Aran-Duchenne) type of progressive muscular atrophy, attacking first the intrinsic muscles of the hands; sometimes of the peroneal type (the legs being involved in about thirteen per cent. of the cases). It affects comparatively rarely the muscles of the larynx. The most terrible cases are those with severe nervous manifestations—the encephalopathic or fulminant cases, resulting, as they do not infrequently, in death after a few hours' illness. The patient, if a girl, is at first probably considered to be hysterical, and shortly develops convulsions, blindness, delirium, and coma. Even if the patient escapes with her life, the result may be persistent blindness, epilepsy, or insanity. Ophthalmoscopic examination often shows double optic neuritis or neuro-retinitis, although there is often amblyopia without fundus changes. Vision may be partially recovered, or absolute blindness may be caused by the atrophy secondary to the papillitis. Permanent blindness more often results, however, from a primary chronic atrophy of the optic nerves. The fits are toxæmic in origin, like those of uræmia and alcoholism, and can only be differentiated from idiopathic epilepsy by a recognition of their exciting cause. In men gout is frequently developed from interference with the excretion of uric acid, and sooner or later cirrhosis of the kidney is set up, to which, in a large proportion of cases, death is directly due. Nearly all female workers in lead are either menorrhagic or amenorrhœic, and abortion is so common as materially to lower the birth rate in some of the affected districts; it is common, moreover, even if the father alone is a worker in lead. In one hundred and twenty-three pregnancies seventy-three children were born dead, and of the fifty born alive only fifteen lived beyond the third year. The children usually die in convulsions, and if they live they are generally ill developed and badly nourished.

Quinine Not a Specific in Malaria.—Dr. James Van Marter (*Gaillard's Medical Journal*, July) believes that if we exclude the simple intermittents, quinine cannot be regarded as a specific, and summarizes briefly his conclusions as follows: (1) As a preventive, quinine will not do for those who are compelled to live indefinitely in a severe malarial climate; in time, it will act as a vasomotor poison. (2) Quinine acts nearly as a specific in all malarial fevers characterized by intermissions or well-marked remissions, but fails in the continued fevers, those with typhoid-like symptoms, those malarias without temperature, and the cachexias and anæmias due to malaria. (3) It is thus proved that quinine is a poison to the plasmodium itself, but useless against the toxin manufactured by it. (4) Warburg's tincture, in the last condition, has an action, not yet understood, on the toxin (or the eliminative system), by which the system is put in condition to benefit by quinine. (5) Quinine should never be used in hæmoglobinuria, or given subsequently to one who has suffered from it, it being liable to bring about a recurrence of the condition. (6) Only those living in regions of severe malarias can become competent to settle these questions *pro* or *con*.

Gynæcological Examination of Women Recently Confined.—Examination is specially indicated when the puerperium has been attended by any signs of infection, and should embrace (1) bimanual examination; (2) inspection of the vulva, vagina, and cervix; (3) investigation of traumatic lesions of the cervix and of the conditions of the cervical mucosa; (4) culture examinations of the cervical secretions; (5) catheterization of the uterine canal, with dilatation if necessary. This will often show the presence in the uterine canal of an abundant brownish or creamy liquid, in which in infectious cases pathogenic micro-organisms are constantly found.—Dr. Doléris, *Bull. Soc. Obst. et Gyn. de Paris*, No. 3.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, October 8, 1898.

THE FOOD SUPPLY OF THE WORLD.

AT the meeting of the British Association, which has lately been held at Bristol, Sir William Crookes dealt at length with this important subject. The view taken in his address at first sight seems a very pessimistic one, and the outlook for the entire world, and especially for those countries which, like Great Britain, depend mainly on outside sources for food, appears to be black to a degree. The eminent chemist predicts —and asserts that his predictions are based upon incontrovertible facts—that in time the wheat production of the world will not nearly suffice for the wants of its inhabitants, and that consequently, unless other means can be devised to meet these wants, there will be universal starvation. Before this point is reached, however, the gloomy forecast is relieved by a ray of light, for the author of the address announces that chemistry will step in and avert the threatened danger. After referring in detail to the present condition of wheat culture in various parts of the globe, and proving by voluminous statistics that under the existing methods of agriculture the supply of bread will after some years be inadequate to the needs of the rapidly increasing population, Sir William Crookes then shows that by the aid of the chemist the grain-bearing capacity of the soil will be almost indefinitely augmented. With regard to what is termed a "dominant" manure, he says: "Wheat pre-eminently demands nitrogen fixed in the form of ammonia or nitric acid. All other necessary constituents exist in the soil; but nitrogen is mainly of atmospheric origin, and is rendered fixed by a slow, precarious process, which requires a combination of meteorological and geographical conditions to enable it to advance at a sufficiently rapid rate to become of commercial importance." The fact is then demonstrated that the supply of nitrogen to be procured by the methods now in vogue is lamentably insufficient, and that the only way in which the difficulty can be successfully overcome is by the fixation of atmospheric nitrogen. Sir William Crookes sketches in these words the probable manner in which this will be effected:

"The fixation of nitrogen is a question of the not far distant future. Let me see if it is not possible even now to solve the momentous problem. As far back as 1892 I exhibited, at one of the soirées of the Royal Society, an experiment on the flame of burning nitrogen. I showed that nitrogen is a combustible gas, and the reason why, when once ignited, the flame does not spread through the atmosphere and deluge the world in a sea of nitric acid, is that its igniting-point is higher than the temperature of its flame—not, therefore, hot enough to set fire to the adjacent mixture. But by passing a strong induction current between terminals, the air takes fire and continues to burn with a powerful flame, producing nitrous and nitric acids. This inconsiderable experiment may not unlikely lead to the development of a mighty industry, destined to solve the great food problem."

The expense of burning out nitrogen from the air, so as to produce twelve million tons annually—the quantity estimated as necessary—with the means at present at our disposal, would be so immense as practically to be out of the question; but that sufficient electricity can be generated to accomplish the desired result is, according to Sir William Crookes, quite within the realms of possibility. He expresses himself on this point in the following words: "A preliminary calculation shows that there need be no fear on that score. Niagara alone is capable of supplying the required electrical energy without much lessening its mighty flow. The future can take care of itself. The artificial production of nitrogen is clearly within view, and by its aid the land devoted to wheat can be brought up to the thirty-bushels-per-acre standard." It is also pointed out that we should not rely on one food stuff alone, but should trust more and more to the exuberant food stuffs of the tropics. The address concludes with this pregnant sentence: "We must develop and guide nature's latent energies; we must utilize her inmost workshops; we must call into commercial existence Central Africa and Brazil, to redress the balance of Odessa and Chicago."

THE DETERMINATION OF SEX IN BEES.

IN the *Archives of Surgery* for August is an article with the above title, which suggests some interesting considerations. Summarized, it is as follows: There are no "neuters" in the beehive. The workers are all females, in whom the sex organs are present but undeveloped. The development of the sex organs depends upon the food supplied to the young bee when in the larval stage. A certain stimulating food "jelly" is given by the bees to any larva which it is wished should grow into a developed female — in other words, a "queen bee." Under the influence of this food the larva grows more quickly, both as regards size and development, than one fed from the common food; and, as a most special feature, its ovaries grow and become capable of forming eggs, without fecundation. The queen bee can at will, if she has once been impregnated, produce eggs which will hatch out either as workers or as drones. If a queen bee has not been impregnated, she can produce fertile eggs, but they will all hatch out males. Sexual impregnation is absolutely necessary to the production of females. Thus it would appear that there may be some truth in the

old belief that males take chiefly from their mothers and females from their fathers, and one can by no means feel certain that prepotency on the part of one or other parent may not have some influence in the determination of the sex of the offspring.

THE MARRIAGE OF THE UNFIT.

Of the many and voluminous articles on the engrossing question as to whether some steps should not be taken to prevent the deterioration of the human race by the marriage of the unfit, probably the most able, and certainly the most noticed, has been one contributed to *The Lancet* of a recent date by Dr. Harry Campbell. Utopian and fantastic plans have of late been freely advocated in the lay press of this country, with the object of legally prohibiting the union of those who are palpably in no condition, physically or morally, to propagate the race. Dr. Campbell, of course, treats the matter from a scientific and medical point of view, and his opinions are well worthy of the closest attention. He first shows to how large an extent the process of natural selection is interfered with among civilized peoples—on the one hand, by a saving of lives which under more primitive conditions would terminate; and on the other, by the restrictions governing the marriage laws. Dr. Campbell appears to think that the abolition of polygamy was, from the standpoint of physical hygiene, a mistake; but, as he admits that the reintroduction of polygamy is impossible, he agrees that the only course to pursue is to attempt to instil into the minds of the community at large the pernicious effects resulting from ill-judged marriages, and asks and answers the question as to who shall and who shall not marry. To the majority of the cases cited by him as unfit, such as pulmonary consumption, organic heart disease, epilepsy, insanity, chronic Bright's disease, no exception can be taken; but it will be generally thought that, as regards one class of disorders at least, he is certainly inclined to be too emphatic in his opinion. We refer to functional disorders of the nervous system. He says: "The highly sensitive are not suited to this hard world. Its strenuous conditions call for men of iron nerve and stout heart. I fear that it must be acknowledged that as regards happiness—which, at any rate from the purely physical point of view, may perhaps be fairly looked upon as our being's end and aim—the fine animal with little imagination and a good thick skin has the best time of it here—is the most truly 'fit.'"

In short, the advice given to those afflicted with "nerves" is, "Remain single." There can be no doubt that if the "neurotics" never married, in the course of time diseases of the nervous system would greatly lessen and probably die out; and it may also be true that a world peopled with phlegmatic, thick-skinned mediocrities would be happier, in a sense. But the question may here be asked: Do we want to be without our "neurotics," or can we get along without them? If history be ransacked, it will be found that most of the great deeds of the world have been performed by individuals of a highly sensitive, nervous temperament. The contention, too, that the thick-skinned mediocrities are the happiest persons is open to doubt. If a more or less animal life is the end to be gained, then they may be; but at the same time the fact should be borne in mind that, while they never descend into the depths of misery, like the being with the ill-strung nervous system, yet, on the other hand, they are incapable of experiencing many of the delightful emotions and of ascending into the heavens of joy, as are the neurotics. In this country the suggestion of Dr. Campbell, that any person afflicted with a neurotic taint should be precluded from marrying, will scarcely meet with favor, as in that case probably half the population would remain single.

News of the Week.

The New Brunswick Medical Society.—The annual meeting of this society was held at St. Stephen, N. B., on July 19th and 20th. The election of officers resulted in the choice of the following to serve for the ensuing year: *President*, Dr. A. B. Atherton; *First Vice-President*, Dr. J. D. Lawson; *Second Vice-President*, Dr. G. T. Smith; *Corresponding Secretary*, Dr. J. H. Scammell; *Recording Secretary*, Dr. G. C. Vanwart; *Treasurer*, Dr. Foster McFarlane.

Cornell University Medical College held its opening exercises on the evening of October 4th, in the building it is to occupy temporarily in the Bellevue grounds until its own building is finished. Dr. Lewis A. Stimson called the students, numbering three hundred and fifty, to order, and introduced President Shurman, who delivered an address. He was followed by Prof. W. M. Polk, dean of the medical faculty, who outlined the work of the session. The new building is to be erected on First Avenue, and will occupy the frontage from Twenty-seventh to Twenty-eighth Street.

Nurses and Nurses.—In a letter from Dr. S. P. Kramer, at Camp Wikoff, to the *Cincinnati Lancet-Clinic*, we find the following interesting comparison: "My experience here has convinced me of some things in regard to nurses. The general hospital here is divided into about two equal divisions, the main hospital and the annex. The former has trained nurses—lay women—under a female superintendent; the latter has Sisters of Charity under a sister superior. Whatever may be the case in civil institutions, in the field hospital the Sister of Charity is far superior. There is with them none of the bickering with the ward doctor, no fussiness, no refusing to perform menial work when necessary, no desire to 'shine,' as is the case with the 'trained nurse.' The Sister of Charity has no ambition but duty; she obeys all orders quietly, with a prompt, orderly, and willing manner. No sacrifice is too great, no service too menial. It has been a matter of general comment here that the annex is a far superior hospital to the main branch, and, to my mind, this is largely due to the presence of the Sisters of Charity in the former."

Idle Physicians.—In commenting upon the fact that within two months after hostilities began over forty-five hundred physicians offered their services to the surgeon-general of the army, the editor of the *Times and Register* remarks: "Ambition and patriotism are all very well to explain this mad rush of an army of nearly five thousand doctors, but, if the facts were sifted, it would be found that in all with few exceptions the real incentive was nothing to do, no practice, and the ghastly spectre of grim want. The writer is familiar with instances where medical candidates, failing to secure entry to the medical department, have gone forward as non-commissioned officers, hospital stewards, and even privates in the ranks."

Violent Surgeons.—Among the deaths from violence noted in the annual report of the Cincinnati health board are three set down as due to surgical operations.

Anthropological Pessimism.—Dr. D. G. Brinton, writing in *Science*, says that there has been a curious tendency during the last decade among European anthropologists toward scientific pessimism. Numerous writers, such as Le Bon, Lapouge, Ribot, Nordau, Vierkandt, Nadaillac, etc., have deplored the traits of modern culture and seen in many of them signs of degeneration. The white race is to be overwhelmed, Europe is to lose its prestige, modern society is to go to the bad. The Latin race is to fall before the Teutonic, the Teutonic before the Slavic, and so on. M. Novicou, in a book called "L'Avenir de la Race Blanche," calls a halt to these lamentations. He argues that when racial, national, and social jealousies cease, the species will be much better off; and what these scientific "calamity howlers" are grieving about is precisely this advancement.

Shortcomings of the British Army Medical and Commissary Departments.—At the same time that reports are published of remarkable efficiency of the medical and commissary departments in the army of Gen. Sir Herbert Kitchener, we hear of the utter breakdown of these same departments in the recent autumn manœuvres of the British army on Salisbury Plain. The London papers say that the soldiers suffered many privations and were without food or drink until relieved by civilians. Many committed offences, for the military prisons had no terrors for them in view of what they suffered in the ranks. The cavalry reached the field without horses enough, and had to hire mounts. There were but two medical officers for twelve regiments, and sufferers from sickness and accident complained of great neglect. Twenty-one injured men were left unattended for hours on a railway-station platform, through some knotting of red tape. So, at least, say the English papers. We quote them merely because misery loves company.

The Medical Society of Nova Scotia. — The annual meeting of this society was held on July 6th. On account of the meeting of the Maritime Medical Association being held at the same date, the session was devoted entirely to business matters. Officers for 1898–99 were elected as follows: *President*, Dr. John McMillan, Pictou; *First Vice-President*, Dr. Andrew Halliday, Shubenacadie; *Second Vice-President*, Dr. M. A. Curry, Halifax; *Secretary-Treasurer*, Dr. W. S. Muir, Truro.—*The Maritime Medical News.*

The First Football Death of the season was reported from Boston on October 1st. A boy, seventeen years old, was thrown during a scrimmage, four or five men of his own and the opposing eleven coming down on top of him. It was not until he tried to arise that his comrades had any idea that he was severely injured. They then found that he was unable to move. At the City Hospital it was found that he was suffering from a fracture of the spine. An operation was performed, but the lad died the following morning.

Portable Army Hospitals.—Sixty portable hospitals, a few for use here but most of them to be sent to Porto Rico and Cuba, are being made for the army. Each building, which will accommodate forty patients, is to be nineteen feet three inches wide and one hundred and twenty-one feet long, to be constructed in sections. There will be forty-four windows and five doors, four of which will be double. Some of the sections will be hinged to allow of speedy exit in case of fire. There will be ample ventilation by means of traps in the ceiling. These buildings are to be constructed of North Carolina pine, set on cedar posts eighteen inches from the ground, and the roofs are to be covered with canvas properly painted. Air ducts are to be provided for those in which it is expected to erect stoves, the ducts in such cases to enter near the stoves. The hospitals for use in the North will have double floors with a felt lining.

Typhoid Fever at Dawson City.—Prospectors returning from the Klondike report an epidemic of typhoid fever at Dawson. Many of the cases terminate fatally.

The University Medical School.—The executive committee of New York University has accepted a deed transferring to the university the new medical college building, begun last year for the Bellevue Hospital Medical College. The university has also received from the former trustees of Bellevue Hospital Medical College the use of the Carnegie Laboratory, with the understanding that the building will become the property of the university when certain conditions are fulfilled. More than $100,000 has been received in gifts during the summer for the University and Bellevue Hospital Medical College, and a medical endowment fund has been established.

The Yellow-Fever Situation in parts of the South is somewhat worse than it was last week. Especially in Jackson, Miss., the fever is spreading in spite of all the efforts hitherto made to prevent it. The total number of cases up to October 2d was 22, with 3 deaths—an increase of 13 cases and 1 death in five days. The cases reported from the several places invaded in Louisiana and Mississippi during the present summer are as follows: Louisiana—Baton Rouge, September 25th, 1 case; Franklin, to September 24th,

106 cases, 5 deaths; Harvey's Canal, to September 24th, 6 cases; Houma, to September 24th, 2 cases, 1 death; Jefferson Parish, September 20th, 5 cases; New Orleans, to September 28th, 12 cases, 2 deaths; Wilson, September 26th, 12 cases. Mississippi—Edwards, vicinity, September 27th, 1 case; Jackson, to October 2d, 22 cases, 3 deaths; Orwood, to September 27th, 67 cases, 3 deaths; Oxford, to October 2d, 14 cases, 4 deaths; Taylors, to October 2d, 84 cases, 8 deaths; Waterford, September 9th, 1 case; Water Valley, September 28th, 1 case; Harriston, October 2d, 3 cases, 1 death. The disease is of a comparatively mild form, as shown by the low death rate.

To Select Camps in Cuba for the Army of Occupation.—The secretary of war has appointed a special commission to select camps for the Cuban army of occupation and to perfect the sanitary arrangements of Havana and other Cuban cities where American troops will be located. The following are the names of those chosen for this commission: Col. G. E. Waring, of New York; Col. William R. Livermore, engineer corps; Col. James C. Lee, quartermaster's department; Capt. Jasper H. Bliss, subsistence department; and Maj. Robert M. O'Reilly, medical department.

Another Transport Scandal has been averted by the action of General Wood at Santiago. He made a personal inspection of the transport *Minnewaska*, which was on the point of sailing with forty sick men, and found that she was unprepared for the trip. Three of the military officers aboard of her were apparently dying, yet there were no nurses aboard, and the supply of food and medicines was inadequate. Not the slightest preparation had been made for the comfort of the sick men. In his report to General Lawton on the subject, General Wood said that great loss of life would undoubtedly have resulted if the *Minnewaska* had sailed in the condition in which he found her, and for this condition of affairs the officers charged with preparing the ship were directly responsible. He detained the vessel for twenty-four hours and had her put in a fit condition for the transportation of the sick.

The Fourth International Congress of Physiologists met at Cambridge, England, during the last week in August. On Tuesday, August 23d, Professor Foster, president of the congress, delivered the annual address, welcoming the congress to Cambridge, and expressing a personal preference for demonstrations rather than dry papers from the members of the congress. A demonstration of great interest was that by Dr. Porter, who showed that (1) the mammalian heart, if kept distended with blood, will, like the frog's, beat for some time after excision; (2) a portion of the ventricle of the excised mammalian heart, suitably fed through a branch of the coronary artery with blood, will go on contracting regularly; (3) the excised mammalian heart will continue to beat if fed with serum only, provided oxygen under pressure be also provided. Dr. Langley showed that, by union of the central end of the cut vagus with the peripheral end of the cut sympathetic, the normal effects of the latter might be produced by stimulation of the former. He concluded from this that all nerve fibres are essentially the same, the difference of function depending on the distribution. Dr. Haldane demonstrated his method of liberating and estimating the amount of oxygen in the blood by means of potassium ferrocyanide. The University of Cambridge conferred honorary degrees on Bowditch, of Boston; Golgi, of Turin; Kronecker, of Berne; Kühne, of Heidelberg; and Marey, of Paris —all of whom were in attendance at the meetings of the congress.

Obituary.

CLAUDIUS HENRY MASTIN, M.D., LL.D.,

MOBILE, ALA.

Dr. Claudius Henry Mastin, one of the leaders of American surgery, died at his home in Mobile, Ala., on October 3d, at the age of seventy-two years. He was born at Huntsville, Ala., on June 4, 1826, and received his academic degree from the University of Virginia in 1846. He immediately began the study of medicine at the University of Pennsylvania, Dr. George B. Wood, of Philadelphia, being his preceptor, and was graduated with the degree of M.D. in 1849. His friends throughout the country had already begun to prepare for the celebration of his fifty-year "jubilæum" next spring. After graduation he went to Europe, and passed five years in study in Paris, London, and Edinburgh, and then began the practice of his profession in Mobile in 1854. Upon the breaking out of the civil war he entered the Confederate army, serving as medical director and later as corps surgeon under General Polk in the army of the Tennessee and elsewhere. At the close of the war he resumed his practice in Mobile. In 1875 the honorary degree of LL.D. was conferred upon him by the University of Pennsylvania.

Dr. Mastin early showed a predilection for surgery, and his skill in operation and ingenuity in devising instruments and special methods for overcoming difficulties amply justified his preference for this branch of the healing art. He was, however, no less a physician, an able diagnostician, and a therapeutist of more than average ability.

A firm believer in the value of association as a means to the betterment of the individual physician as well as to the increase of the general fund of medical knowledge, Dr. Mastin was always prominent in medical societies. He was one of the original members of the American Surgical Association, of the American Genito-Urinary Association, and of the Southern Surgical and Gynæcological Association. He was also credited with being the originator of the idea of a general congress of special societies to be held at some central point at stated intervals, and it was in conformity with a suggestion offered by him in 1885 that the first Congress of American Physicians and Surgeons was assembled in Washington in 1887. He was a member, either active or honorary, of a great number of other medical associations, and was a prominent figure at the meetings of many of the local and national societies.

Dr. Mastin always kept in close touch with his medical alma mater, the University of Pennsylvania, and was a member of the central council of the university as well as one of its examining-board. He was a frequent contributor to medical literature, and his fame as a surgeon of superior parts was world wide.

Clinical Department.

DIPHTHERIA COMPLICATED BY MEASLES; HYPERPYREXIA; RECOVERY.

By L. E. LA FÉTRA, M.D.,
NEW YORK,
ADJUNCT LECTURER, DISEASES OF CHILDREN, NEW YORK POLYCLINIC.

The patient, Louisa K——, six years old, was first seen on the morning of Tuesday, March 15th. On Sunday she had gone out of town to spend a few days, but returned ill on Monday.

I found the girl fairly well nourished, though slightly anæmic. Respiration was difficult and noisy, the mouth being held open and the tongue protruded; the breath was very foul. There was a grayish nasal discharge, tenacious and excoriating. Below the angle of the jaw on either side was a tender swelling, about as large as a goose egg, flattened and irregular in shape, so as to extend as low down as the cricoid cartilage and upward on to the body of the lower jaw. Four or five enlarged glands were felt in the indurated mass; no fluctuation. The tonsils had been removed some months previously, but their stumps were covered by a grayish membrane—more extensive on the left side, where it had already begun to pass up on to the soft palate. Temperature, 101.2° F.; respiration, 28; pulse, 104. The diagnosis was nasal diphtheria extending to the pharynx. Accordingly fifteen hundred units of antitoxin were given immediately—that being all then at hand—and cultures were made from the nose and throat. Both cultures showed the Klebs-Loeffler bacillus in abundance. Hourly nasal irrigations—one ounce of hot saline bichloride (1 to 5,000) for either nostril—were ordered, the method of irrigation being that described by Holt ("Diseases of Infancy and Childhood," 1898, p. 57). The nurse was instructed to persist in her efforts to make the liquid run through, either into the pharynx or out the opposite nostril; this because of the nasal obstruction existing even after some of the membrane had been removed with a cotton swab. The child received also five minims each of tincture of the chloride of iron and tincture of nux vomica, with two teaspoonfuls of whiskey every two hours.

By six o'clock that evening the membrane covered nearly the whole of the soft palate and uvula, and the faucial pillars were very œdematous; the nasal discharge was more profuse. The dyspnœa was very distressing, but intubation was not performed, because the obstruction seemed to be altogether above the larynx. Two thousand additional units of antitoxin were given, and the two other children, one of whom had measles, were immunized. Isolation of the children from each other was carried out as thoroughly as possible. On the second day after the antitoxin had been given, small fragments of membrane began to come away. Irrigation was made every three hours.

Then for four days the child improved, the nasal discharge ceasing, the membrane clearing off, and the swelling in the neck diminishing. But on March 21st the temperature, which before had ranged from 100° to 102°, and was falling, went up to 103° F., and an atypical erythema appeared on the abdomen near the site of the antitoxin injection; there was also some erythema on the neck. There was no coryza, laryngitis, or bronchitis. The question was whether this was an antitoxin rash or measles, or both combined; and the case was as puzzling at first as any of those reported in Berg's article on the "Antitoxin Exanthemata" (New York Medical Record, June 18, 1898), for the rash was atypical in appearance and distribution, and there were no catarrhal symptoms. On the inside of the cheeks, however, a few of the measles spots described by Koplik were found; and these, so far as I know, have never been observed as part of an antitoxin exanthem—even of the morbilliform variety. By the next day the eruption was typical, though accompanied by an unusual amount of œdema. The temperature, March 22d at 10 A.M., was 105.6° F.; at 6 P.M. it had risen to 106.4° F., and the child was prostrated. Cultures from the throat were negative. By 10 P.M. the temperature had risen to 107° F. The next day the temperature had fallen about a degree and a half, and the child was more comfortable. The further history of the case was not unusual.

The case is reported because of the following points of interest: 1. The early and extensive swelling of the cervical lymph nodes—not unusual in cases beginning as nasal diphtheria. 2. The early loosening of the membrane—on the second day after antitoxin; and its complete disappearance on the fifth day. 3. The absence of catarrhal symptoms at the onset of the measles, and the hyperpyrexia during the development of the eruption.

PHANTOM TUMORS IN A MAN.

By BENJAMIN K. HAYS, M.D.,
OXFORD, N. C.

T. B——, a white man, forty years of age, consulted me in regard to two tumors in his side. Upon examination I found deep-seated nodular enlargements in both lumbar regions. The abdominal muscles were tense, and the enlargements felt like cocoanuts situated beneath them. He was suffering from acute melancholia, and informed me that I was the twenty-third doctor he had consulted. The only pleasure he seemed to have in life arose from the perplexity he caused the doctors and the ability to inform me at each visit that he was "worse." Believing that his "tumors" were in part at least the result of the morbid condition of his mind, I put him under the influence of chloroform, whereupon the swellings entirely disappeared.

ANGINA LUDOVICI COMPLICATING AN ACUTE SUPPURATIVE OTITIS; RECOVERY.

By M. D. LEDERMAN, M.D.,
NEW YORK,
LECTURER ON DISEASES OF THE NOSE AND THROAT, NEW YORK POLYCLINIC; ASSISTANT AURAL SURGEON, MANHATTAN EYE AND EAR HOSPITAL; FELLOW, NEW YORK ACADEMY OF MEDICINE, ETC.

In reviewing the literature pertaining to this serious form of infectious cellulitis, I have not been successful in finding a record of a similar instance. For this reason, if no other, the report of this case will no doubt prove of more than passing interest. Infectious phlegmon attacking the floor of the mouth is in itself a rare manifestation, and usually follows some form of traumatism, disease of the teeth, or infection arising from adjacent tissue. In the case which came under my observation, the pathogenic factor had its origin in an acute suppurative otitis.

Miss R——, nineteen years of age, consulted me on account of a very painful ear. She was recovering from an attack of "cold in the head," but found that after the increased nasal secretion had subsided there was a decided sense of fulness in the left ear, which gradually became very painful. During the night she suffered intensely, and the following morning presented herself for treatment.

On examination, a well-marked attic inflammation could readily be seen, with considerable bulging of that portion of the membrana tympani. Some tender-

ness existed over the mastoid region, though no prominence of the posterior canal wall could be observed.

An incision was made through the bulging portion of the drum, and carried forward so that free drainage should be established. In such cases mere paracentesis does not accomplish the desired result, as the folds of mucous membrane which line the vault of the middle ear act as a ball valve, and, if not incised, obstruct the necessary drainage. Consequently, in attic inflammations with indications that point to retained contents, it is always judicious to make an inverted L incision, through the postero-superior quadrant. Ice was ordered to be applied over the mastoid for a few hours. The patient passed a poor night, and, as she was not able to call at my office the next morning, the treatment was continued at her home. Rest in bed was advised, as the temperature was 103.4° F., with a pulse of 120.

Finding the drum still bulging, I made another incision through the postero-superior quadrant, and carried it across to the anterior periphery of the drum. Some blood and pus followed this incision. The posterior canal wall showed no signs of mastoid invasion, though deep pressure over the process elicited some tenderness. Ice applications were continued for four hours, and a hot aural douche was used every two hours.

During the second night the ear was quite comfortable, although Miss R—— complained of pain, similar in character to a sore throat, but not definitely located. This symptom rapidly became worse. Difficulty in swallowing was also noticed.

On my examination on the third day, the ear was found much improved; the swelling of the drum had almost disappeared, and there was but little soreness present, although some discharge flowed from the ear. The mastoid tenderness had disappeared completely. To my unpleasant surprise, however, the patient was not able to speak distinctly. Saliva was flowing from her mouth, and her face had the expression so frequently seen in cases of peritonsillitis. She was unable to swallow solid food, and it was only after considerable effort that liquid could be taken. No disease of the fauces or larynx could be found after a difficult examination, but the sublingual tissues along the floor of the mouth on the left side were somewhat swollen. The temperature was 101.4° F.; pulse, 110. The ear had given no trouble during the preceding few hours, but the trouble in the mouth caused much annoyance. Syringing of the ear was continued, and an antiseptic mouth wash was prescribed, to be employed after being heated. No disease of the teeth could be found from a cursory examination.

At the next visit, on the fourth day, the patient presented a characteristic and serious aspect. The left side of the neck was decidedly swollen and very painful to pressure. The chain of cervical lymphatics could be distinctly felt. The external swelling was very tense, without fluctuation. My patient's expression was one of great suffering, intensified by the appearance of the tongue, which was pushed over the edge of the lower teeth, on account of the marked swelling of the sublingual tissues. The flow of saliva was constant, and nothing could be swallowed, as the movement of the tongue was restricted. After repeated attempts a pharyngeal and laryngeal picture was obtained, but no œdema of these parts could be seen. Breathing was not materially affected. Though the tongue was normal in size, it appeared larger, owing to its protrusion. No distinct fluctuation could be felt in the swelling along the floor of the mouth. At a point near the frænum on the left side, the mucous membrane seemed changed in color.

It being realized that œdema in this region is very apt to assume dangerous proportions, surgical exploration was decided upon without delay. The parts were cocainized and three deep punctures were made into the swollen tissues on the left side. The first puncture was made near the lingual frænum, the second about an inch farther posteriorly, and the third about half an inch farther back but more exteriorly. I was agreeably surprised to find that pus followed the first two incisions. These punctures were dilated by means of a grooved director. Pressure over the external swelling of the neck augmented the discharge of pus. Hot bichloride-of-mercury solution (1 to 4,000) was ordered as a mouth wash, to be employed hourly. Pus continued to be discharged for four days, and under ichthyol applications the cervical swelling gradually disappeared. The ear had ceased discharging at this time, and no further trouble was experienced. General tonic treatment was indicated for some time after her convalescence.

Infection in this case no doubt arose from the severe acute suppurative otitis. This occurred through the lymph channels, as the cervical lymphatics were swollen and painful. It was interesting to observe that as the phlegmon progressed the ear symptoms gradually subsided. The fortunate location of the incisions certainly avoided radical external exploration, and showed that the disease was still involving the superficial tissues. A delay of twenty-four hours would no doubt have caused a serious, if not a fatal termination.

Angina Ludovici must be regarded as a very treacherous disease, in which the prognosis is exceedingly dubious. No time should be wasted in employing tentative measures. Free incisions must be made whenever œdema makes its appearance under similar circumstances.

38 East Sixtieth Street.

A CURIOSITY IN A CASE OF LOCOMOTOR ATAXIA.

By FREEMAN F. WARD, M.D.,

NEW YORK.

Thomas M——, aged fifty-three, came to the clinic at the Roosevelt out-patient department, complaining of trouble with his stomach, and gave the following history: His mother died of phthisis and his father of Bright's disease, but neither had any history of specific disease. His present trouble began fourteen years ago with gradual failure of vision, extending over a period of four years, when he became totally blind. About this time he began to experience some numbness of the feet and lower extremities, which he attributed to his sitting so long in one position, his occupation being that of a driver. He also had at this time more or less incontinence of urine and constipation. It is only during the past six or seven years that he has had what he could call real pains in the calves of his legs. His main suffering at the present time is severe pain in the region of the stomach. This pain is almost constant and unassociated with taking food.

Condition at present. Optic atrophy, with total blindness; feeling of tightness in the head; more or less pain in the lower extremities, but pain most marked in the gastric region; girdle sensation in slight degree; incontinence of urine; obstinate constipation; absolute loss of knee jerk; marked impairment of muscular sense, bringing out most strikingly the helplessness of a blind ataxic; inco-ordination and imperfect muscular tone very marked.

The curious point of the case lies in the symptom of Romberg. Although the patient is perfectly blind, he can stand with his feet close together quite well, with only slight swaying; but the moment he closes his eyes he begins to sway and would topple over if

left to himself. The symptom seems to be brought out only by the act of closing the lids, and not simply from the shutting out of the light. The question arises, Is the symptom of Romberg produced or brought out in any case, even when optic atrophy is not present, by shutting out the light or by the act of closing the lids?

I report the case as one of possible interest solely on account of this peculiarity, for in talking with several physicians especially interested in nervous diseases, to whom I have shown the patient, I have found none who ever before observed such an instance.

6 East Fifty-eighth Street.

SOME INTERESTING EYE CASES.

By W. L. GRANT, M.D.,

Fargo, N. Dak.

E. M——, aged thirty-two, was a colored musician of a low class, doing night work in a Moorehead brothel. He was of magnificent physique and in perfect health. On the morning of June 14, 1898, between five and six o'clock, he took part in a drunken brawl in a saloon next door to the place where he was employed, and while on his back was struck in the eye by his antagonist's heel. He was immediately brought home in a cab, and a lotion, put up by a druggist, was applied to the eye. The principal ingredient of the lotion was hamamelis. He suffered considerably for an hour or so after the accident, but had no pain after that. The case was referred to me by Dr. Henning, of this place, and I saw the patient the same evening. I found considerable ecchymosis and œdema of the lids, a bruise in the sulcus of the lower lid, three-fourths inch long and showing peg marks, and much swelling of the conjunctiva. The sclera was ruptured for one-half inch, the line of rupture extending from quite near the inner canthus downward and outward in a slightly curved direction, and passing in front of the insertion of the inferior rectus. This caused the eye to turn upward, and it was impossible for it to be brought downward by any muscular action. Opening the opposite eye (the left) caused pain in the injured organ. Enucleation was advised, but refused for a time. On the 15th the injection was increased. On elevation of the lid the conjunctiva rolled out in a large firm welt. The man now agreed to the operation, which was done the next morning, with the assistance of Dr. Lorkness, as Dr. Henning, who referred the case to me, was unable to be present. The operation was done in a living-room in a flat, where one room served for a family and the surroundings were not of the best. The globe having been caught up with a small tenaculum, the muscles were divided one after the other and the collapsed organ was removed. In addition to the rent described, there was a second and shorter one above and slightly to the outer side, passing behind the superior rectus insertion. There was little or no hemorrhage either before or during the operation. Two hours after the operation (chloroform was the anæsthetic used) the patient complained of being hungry, and ate a pound of beefsteak. He remained in bed twenty-four hours, and in the house twelve hours longer. Recovery took place promptly and without incident. He was ready to go to work inside of a week.

G. H——, aged twenty-five, a student at the Agricultural College, whose home was at Devil's Lake, N. Dak., consulted me, March 25, 1898, regarding a pterygium of the right eye. He said he had been suffering slightly from a cold for a few days, but wanted operation at once, so as to be able to get home as soon as possible. The growth was removed, but instead of the patient putting in an appearance at my office the next morning his roommate came, saying he was in bed with measles. Notwithstanding this, the wound healed kindly, and I did not notice that there was a departure in the healing process from the ordinary. I would not be inclined knowingly to undertake any operative work upon an eye at the beginning of an attack of measles, but here there was no harm done.

F. L——, aged thirty-five, a Scandinavian coal miner, of Lehigh, Iowa, consulted me, July 16, 1897, regarding an injury received while at work in the mine three days before. Walking past a blast which he did not know was loaded, he received the discharge in the face, and the skin and conjunctiva were peppered with bits of coal and grains of powder. He had been using, on his physician's advice, a lotion of boric acid. There had been some pain from the time of injury. I found, in addition to the above-mentioned markings, a wound just at the junction of the cornea and sclera above, a little more than one-fourth inch in length, and filled with bits of powder and coal. After cleansing, I found the sclera was not penetrated. There was much injection of the conjunctiva about the affected area, and pain was more severe than at first. I cauterized the wound throughout its full extent with carbolic acid, ninety-five per cent., gave the man atropine-sulphate solution, one per cent., continuing the boric-acid lotion at the same time, and put on a bandage. The cauterization was repeated two days later. There was no more pain, and healing took place promptly, with vision unimpaired.

608 Front Street.

SKIN GRAFTING BY UNUSUAL METHODS.

By FRANK OVERTON, A.M., M.D.,

Patchogue, N. Y.

On October 11, 1897, O. M——, aged thirteen, had three fingers of his right hand crushed between two rollers, so that spontaneous amputation took place at the first joint of each, leaving the proximal phalanges denuded of skin, but with the bones covered with granulations. On November 4th I covered the granulations with the lining membrane from the shell of a hen's egg, applying its inner surface to the finger. The egg was used immediately after it was laid, and it was kept in warm water during the operation. There was difficulty in immobilizing the fingers, and so most of the grafts were rubbed off, but a piece one-fourth of an inch square adhered to the base of one finger and formed an islet of epithelium, which, however, spread somewhat more slowly than ordinary epithelium. A few days later grafts of epithelium were shaved from the patient's arm and applied to the fingers, but most of these were rubbed off. Those that did grow had the same appearance as the grafts from the egg.

On December 29th, at 2 P.M., I amputated a foot for a gunshot wound. Placing the foot in my carriage, I drove three miles to my office with the temperature at zero. I then shaved off thin grafts of epithelium and preserved them on glass at the ordinary temperature of my office until I could send for the boy and graft them on his fingers, which was done at 7 P.M. These grafts grew as well as those from the normal skin. Between the three methods a good skin finally covered the stumps and put an end to further experimenting.

In the Medical Record for April 4, 1896, I reported a case of skin grafting in which the epithelium was raised by means of a cantharides blister. That and the present case illustrate methods of obtaining grafts when they cannot be procured in the usual way.

A FORM OF AMBLYOPIA.

By NORBURNE B. JENKINS, M.D.,
KNOXVILLE, TENN.

It will be observed in those individuals in whom there is a difference in the refraction of the two eyes, and more especially in those anisometropes in whom in one or both eyes there is one-half diopter or more of astigmatism, that usually after the fifty-fifth year and occasionally at an earlier age an amblyopia of one eye often manifests itself.

The amblyopia here described is analogous to the amblyopia ex anopsia of early life, from which it differs in the following essentials: It readily yields to treatment; it is rarely accompanied by strabismus, which, when present, is divergent and of so slight a degree as to require no surgical interference, as the restoration of binocular single vision is simultaneous with the complete return of vision to the amblyopic eye; it tends to progress rapidly until only a perception of light remains; as a rule, it is the less ametropic eye which becomes amblyopic; it may occur in an emmetropic eye, provided its fellow is ametropic.

The vision of the amblyopic eye depends upon the progress of the suppression of the retinal image, and varies in different subjects from a perception of light only to a vision in the initial stage, but slightly subnormal. The field of vision is contracted in proportion to the loss of vision, and gradually increases with the improvement of the vision until it resumes its former normal extent. The fundus oculi presents no changes in this functional impairment, which possibly heretofore has been confused with those forms of amblyopia and amaurosis in which the ophthalmoscopic signs are normal or nearly so.

It is to be understood that the etiological factor in those cases is principally an improperly corrected presbyopia, and in some instances an uncorrected or an improperly corrected ametropia. This serious type of retinal-image suppression will clearly demonstrate the disastrous consequence of the routine practice of placing on the eyes of the aged spherical lenses, both of which are of the same focus, notwithstanding there exists in a large percentage of persons a tangible anisometropia.

Of the various forms of amblyopia, this one is probably the most amenable to treatment. When this is begun an immediate improvement from day to day is noticeable, and then from week to week a gradual increase of the vision and of the field of vision is perceptible, until finally the complete function of the eye is restored.

The above-described condition is by no means of rare occurrence. It possibly exists more frequently than any other form of blindness, and is entirely at variance with the accepted theory that "after the complete development of the functional capacity of the retina it will not be materially impaired by non-use."

Below is the history of an incipient and another of a developed case of this amblyopia:

Mrs. ——, aged thirty-seven; neurasthenia; has been for years under the care of physicians. In the last fifteen years the patient has been tested for glasses by five oculists. Until recently the vision of the right eye was decidedly better than that of the left.

June 20, 1898. Patient states that the vision of the right eye has recently become as defective as that of the left. Wearing for near vision: R. E., + 1.50 S.; L. E., + 1.75 S.

June 20th to 24th. R. V., $\frac{6}{15}$; $\frac{6}{6}$ with + 5 S. combined with — 0.50 C., axis 105°; $\frac{6}{6}$ with + 4.50 S. combined with — 0.50 C., axis 105°; $\frac{6}{6}$ is the best vision obtainable. L. V., $\frac{6}{15}$; $\frac{6}{6}$ with + 5.50 S. combined with — 1 C., axis 90°; $\frac{6}{4}$ with + 5 S. combined with — 1 C., axis 90°.

July 30th. R. V., $\frac{6}{9}$; $\frac{6}{6}$ with + 5 S. combined with — 0.50 C., axis 105°; $\frac{6}{4}$ with + 4.50 S. combined with — 0.50 C., axis 105°. L. V., $\frac{6}{15}$; $\frac{6}{6}$ with + 5.50 S. combined with — 1 C., axis 90°; $\frac{6}{4}$ with + 5 S. combined with — 1 C., axis 90°.

Mr. John W. D——, aged sixty-five; robust health; in the civil war was a gunner of company B, first Tennessee light artillery. As a gunner, the patient claims that he had no superior. With a James rifle, carrying a twelve-pound shot, he was able at the extremest range of this gun to hit the smallest target. Until one year ago the right eye only was used in shooting. At the age of forty-five glasses were needed for near vision. Four years ago he killed squirrels with a rifle. Two years ago his sight was in condition successfully to shoot a small target gun. He noticed no impairment of the vision of the right eye until about twelve months ago, when a haziness manifested itself, which gradually increased until the sight was lost. Previous to this impairment the vision of the right eye was considered perfect.

April 11, 1898. R. V., perception of light. Wearing for near vision: O. D., + 3 S.; O. S., + 3 S.

April 25th. Counted fingers at one meter, and saw a white door knob across the room. Field of vision much contracted.

May 10th. With + 4 S. combined with — 0.75 C., axis 180°, read newspaper advertisement in large type.

May 25th. With + 4 S. combined with — 0.75 C., axis 180°, read No. VII. near-vision test type.

June 1st. With + 4 S. combined with — 0.75 C., axis 180°, read No. V. test type.

June 15th. With + 4 S. combined with — 0.75 C., axis 180°, read slowly No. I. test type. Distant vision slightly less than that of left eye. Field of vision somewhat contracted.

April 11th. L. V., $\frac{6}{15}$. Near-vision refraction of left eye: + 5 S. combined with — 2.50 C., axis 20°.

A NOTE ON CONSERVATIVE SURGERY OF THE THUMB.

By JOS. H. BALL., M.D.,
TUCSON, A. T.

A GUNSHOT wound of the hand was my first surgical case in private practice. A Frenchman and his son were in a small rowboat at Rockaway Beach, lying in wait for wild ducks. The son held the oars and the father was ready to fire. While the latter watched the birds afar, the gun went off and the contents of the cartridge, acting like a bullet, carried off the whole thenar eminence of the son's right hand. The shaft of the first metacarpal bone of the thumb was shot away. Some splinters, attached to the articular heads, were hanging about the wound. When the hemorrhage was stopped, the wound cleaned of powder, wadding, and stray shot, and when the splinters were snipped off, it was interesting to note the action of the remaining muscles of the thumb deprived of their lever. Movements of flexion, extension, abduction, and adduction could obviously have but one result—shortening and lengthening of the thumb on its axis. A thumb acting like a jack in a box would seem to be useless. The question of amputation was unavoidable. The patient remarked that if the thumb proved to be an obstruction it would be time to lop it off later on. His wish was acceded to, as there seemed to be nutrition enough left for the thumb. Under ordinary antiseptic dressings, granulations soon sprang up and filled the gap. Peruvian balsam and compression with narrow strips of adhesive plaster were used later on to hasten the formation of the skin. In about three months repair was complete. During this

process the thumb slowly shortened. The articular heads of the bone were brought into contact and united. For the first six months the various movements of the thumb were barely perceptible. Little by little they became more marked. The patient could now hold light objects with his diminutive thumb. He continued exercising it. After a year he could again wield the sledge hammer, with measured beat and slow, in the Woodhaven agateware factory, as though his thumb had never been in danger of being snipped off by one cut of the surgeon's scissors.

The practical conclusion to be drawn from this case is that even if the whole first metacarpal bone of the thumb is shot away, no amputation should be made. The thumb will become shorter, but will be practically as useful as if no accident had happened.

A few days ago I saw a Mexican with a thumbless right hand, a rifle ball having broken the first metacarpal bone. It is easy to imagine the lifelong misery of a Mexican unable to roll his cigarettes. The sight of such wretchedness induced me to relate my case.

A CASE OF ANNULAR SCOTOMA.

By C. N. B. CAMAC, M.D.,

NEW YORK.

Owing to the rarity of this condition, the following case may be of interest:

For two days Mr. O. J—— had been taking a preparation containing ferri et quininæ citras and quininæ bisulphas. When seen he had taken a little over thirty-six grains in the two days, at the rate of about six grains thrice daily. At 9:30 A.M., while sitting at the breakfast table, he experienced a sensation as of "looking through tubes." He could not see objects to the right or the left or below him while holding the eyes fixed; only such objects as were directly before him were visible. He was conversing with some one across the table at the time, and those on either side of him as well as those on either side of the person to whom he was speaking were wholly out of his field of vision. In order to see his plate and so on, it was necessary for him to bend the head directly down. He could not recall having attempted to see objects above him. He was concerned about his condition, but he was in no other way incapacitated; there was no sensation of nausea or fainting. The condition lasted about half an hour.

This patient is a subject of hypermetropia, which is corrected by glasses. The field of vision is but moderately contracted, about equally so in both eyes. He is of a stable nervous disposition.

I. E. Atkinson, in the *Journal of the American Medical Association* (1889, vol. iii., pp. 413–446), gives a very complete account of the toxic effects of quinine on the eyes, but cites only one case of the annular variety. De Schweinitz in his Alvarenga prize paper quotes Atkinson as mentioning only this one case. A similar case, but of longer duration, occurred during my term as first assistant in Dr. Osler's clinic in the Johns Hopkins Hospital. This case has not, to my knowledge, been reported.

Amaurosis is reported by De Schweinitz to have lasted in one case two years, but no permanent cases are recorded. The minimum dose, according to De Schweinitz, capable of producing toxic eye symptoms, is fifteen grains; smaller doses than this are cited by him as having produced partial amaurosis of short duration.

The condition, while alarming to the patient, is neither of long duration nor followed by any serious disturbance of vision, and would tend to indicate an idiosyncrasy to quinine.

Surgical Suggestions.

Removal of Cerumen. — Hard plugs of wax are sometimes difficult to remove at one sitting by mere syringing. Ricci finds that the cerumen is quickly softened by peroxide of hydrogen. The meatus should be filled with the drug, and after soaking for a few minutes the ear should be syringed with hot water. The process may be repeated if necessary.—*Annal. des Mal. de l'Or.*, April.

How to Perform Paracentesis of the Membrana Tympani.—Dr. Grüber gives the following directions in the *Rev. Hebd. de Lar., Otol. et Rhin.* When the exudation is quite fluid, or when a less fluid exudation is small in quantity, limited to the anterior portion, and not displaced by the air douche, the incision should be made in the antero-inferior quadrant. When, on the contrary, the exudation is more or less thick and is very abundant, a long curved incision should be made from above downward, parallel to and about one millimetre from the posterior attachment of the membrane. A kind of curved lid is thus formed, which allows of a ready escape of pus, and this may be hastened by aspiration of the meatus with Siegel's speculum.

Foreign Bodies in the Ear.—Hummel (*Münchener med. Woch.*) makes the following deductions: (1) The relation of the normal ear canal to inanimate foreign bodies is entirely without reaction; that is, the foreign body in the ear does not, *per se*, endanger the integrity of the ear. (2) Every hasty endeavor at removal is, therefore, not only unnecessary, but can become very injurious. (3) In all cases not previously interfered with (with few exceptions), the foreign substance can be removed from the ear by means of syringing. (4) The general practitioner should never employ anything but the syringe in his endeavors to remove foreign bodies from the external auditory canal. (5) An instrumental removal of a foreign body from the ear should be effected only by one fully able to examine the ear with an otoscope and acquainted with every operative manipulation in this region.

Forcible Reduction in Pott's Disease.—(1) Forcible reduction in Pott's disease involves danger to life; this is, however, not sufficiently great to banish it as a warrantable procedure, and especially in properly selected cases. (2) The reduction of firmly ankylosed kyphosis is to be condemned. (3) The justifiability of reducing a gibbus involving a considerable number of vertebræ is doubtful. (4) The application of this method is justifiable in cases of paraplegia when the older methods of immobilization have failed. This method is probably no more dangerous to life than are the bloody operations for this purpose. (5) It is exceedingly probable that many kyphoses treated by this method will recur. (6) Forcible reduction may prove of great value in severe rachitic scolioses and kyphoses, and under these conditions will probably be found to be almost without danger.—Dr. Albert H. Freiberg, *Cincinnati Lancet-Clinic.*

Operative Interference in Epilepsy. — From the evidence now at hand, the operative surgery of epilepsy must be regarded as an experiment with a very uncertain future. The facts at our disposal seem to indicate that while trephining may be a justifiable measure in these cases, the careful and conscientious surgeon must warn his patients and the parents not to be too sanguine of good results. Statistics seem to prove that operative measures should be employed only in traumatic cases in which there are localizing

features, such as a depressed fracture, a scar from an old injury, or focal manifestations on the part of the brain.—J. C. Oliver.

Mortality of Prostatectomy.—The mortality after prostatectomy is still high—about eighteen or twenty per cent. for all operators. It is gradually becoming less as the indications for the operation are better understood. The death rate of individual operators will undoubtedly continue to grow less as they become more expert in performing the operation, and the cases of relapse and failure will be much fewer as more experience is gained.—Alexander.

Fistula in Ano.—According to Dr. Cooke, the following important points should be observed: (1) A careful physical examination of the lungs as well as of the entire rectum is to be made in every case. (2) Pulmonary tuberculosis is not necessarily a contraindication. (3) Do not put down the knife until certain that every sinus has been divided. (4) Remove all diseased tissue. Large wounds are not to be feared. (5) Caution: the sphincter is to be divided only once and at right angles. (6) Special attention is to be given to the mucous opening. (7) Invasion of the perineum must be avoided, especially in females. (8) Systematic antisepsis is necessary if good results are desired. (9) Care and patience are required in the after-treatment. Dressings are not to be left to the family nurse. (10) In the after-treatment two warnings are to be heeded; complaints of unusual pain by the patient and increase of the discharge. Either of these may mean the formation of another abscess. (11) Hemorrhage and incontinence of fæces are the chief danger. Both are amenable to treatment and should not deter from the operation.—*Medical News.*

Suggestions.—Never allow rubber plaster to come in contact with a surface uncovered by normal skin. Since it cannot be sterilized by heat, it must be considered as being dirty. Before operating, always find out whether the patient has any malarial history. The discovery of this fact will save you many a bad scare when temperature rises suddenly after operation. As long as any urine issues from the urethra it cannot be said that there is an impassable stricture. Patience and gentleness will do wonders. The most skilful surgeons see very few strictures that prove impassable. An aseptic dressing placed over a wound that is expected to unite by first intention should be left undisturbed until it is time to remove the stitches, or until there is reason to believe that the case is not running the expected aseptic course. If you find albumin in the urine before operating for pelvic trouble, remember that it may be due to cystitis and not to a nephritic condition. Investigate microscopically or by catheterization of the ureters if possible. Albumin does not signify much if casts are persistently absent. Fishbones stuck in the pharynx are nearly always inserted upon the lateral walls, a little above the aryepiglottic fold. It is often difficult to detect them with the mirror. Spray cocaine and search with the finger, remove with forceps, and warn the patient that he may feel for a long time as if the bone was still in position. Wherever large wet dressings are indicated for a long time, we often find that all of the antiseptics now in use may cause an eczematous condition of the skin, unless so diluted that their antiseptic power is more than doubtful. In such cases the employment of simple saline solution is frequently of the greatest value, cutaneous irritation seldom follows its use, and wounds do as well as with any of the antiseptics. Do not cauterize infected wounds, unless it is to obtain a moral effect in a scared patient. It was shown more than fifty years ago that when horses were inoculated with glanders, and sheep with pox, cauterization with a red-hot iron, applied ten minutes after inoculation, failed to check the disease. An infected wound should simply be well laid open and covered with a wet dressing. The use of nitrate of silver to cauterize wounds is a harmful absurdity.—*International Journal of Surgery.*

Tuberculous Abscess.—After evacuating the pus inject ol. cinnamomi, 10; ol. sterilisat. q.s. ad 100.—Mariotti.

The Operative Treatment of Irreducible Subcutaneous Fractures.—Ransohoff, in an article on this subject, believes that in certain cases an interference before union had resulted would be preferable to the certainty of deformity, and reports seven cases which have come under his observation in which the fracture was exposed and directly treated. The author states that his experience or what he has gleaned from literature does not warrant him in coming to conclusions that are final. Nevertheless, he believes that it would be justifiable to submit in a tentative way to the following postulates: (1) The conversion of a simple fracture is justifiable when other means to secure the best end results fail. (2) In fractures of the diaphysis of the tibia, femur, humerus, and clavicle, in which insurmountable longitudinal displacement or axial rotation has taken place, immediate operation or mediate operation before definite union has occurred is indicated. (3) In epiphyseal separations, when reduction cannot be otherwise effected, an early operation is justified. (4) Fractures complicated with dislocations irreducible by other methods warrant operative interference. (5) The involvement of a joint, except probably in the case of knee and hip, does not, *per se*, militate against operation if this is otherwise indicated. (6) If extensive comminution is present, as in compression or crushed fracture, operation is contraindicated. (7) Special precautions against infection must be taken, in connection with which should be borne in mind the dangers of too firmly closing a wound and the advantage of temporary tamponade and secondary suture. (8) Reckless and indiscriminate resort to the operative relief of deformity in recent simple fractures is to be condemned, since there would be few fields of surgery, in the event of an unsuccessful intervention, in which the contrast could be greater between the good intended and the harm done.—*Boston Medical and Surgical Journal*, June 23d.

Fowler's Method for the Radical Cure of Inguinal Hernia.—Dr. G. R. Fowler sums up the essential steps of the operation as follows: (1) A curved skin incision which furnishes easy access to all the parts involved in inguinal hernia. (2) Splitting the anterior wall of the inguinal canal from the external to the internal ring. (3) Isolation of the cord and sac together from the surrounding parts, after which these are separated from each other and cleared well up to the internal ring. (4) Double ligature of the deep epigastric artery, with sufficient space between the ligatures to permit of incision. (5) Cutting away of the neck of the sac and incision of the posterior wall of the inguinal canal and Hesselbach's triangle. (6) The cord is transplaced into the peritoneal cavity from the site of the internal to a point below the level of the pubic bone. (7) Broad approximation and suturing of the peritoneum and transversalis fascia in front of the cord for the space mentioned. (8) Obliteration of the internal ring and inguinal canal by accurate suturing, and strengthening of Hesselbach's triangle and the new point of emergence of the cord by outward displacement of the pubic attachment of the corresponding rectus muscle.

Aneurism of the Aortic Arch.—Dr. B. Merrill Ricketts (*The Journal of the American Medical Association*, vol. xxxi., No. 7) submits the following conclusions: (1) The remedy lies within the domain of surgery. (2) There are but two such methods at the present time to be considered: (*a*) Obstruction of the right subclavian and common carotid arteries; (*b*) introduction of wire or needles into the sac, with or without galvanism. (3) Either one or both of the operations should be applied in all cases after a thorough saturation with the iodides. (4) Ligation is attended by less danger, less mortality, greater and more permanent and universal benefit. (5) Ligation of the subclavian and common carotid arteries is less dangerous than ligation of the innominate. In point of fact, the latter should not be done. (6) The iodides should always precede and follow any surgical interference. (7) Extreme atheroma might contraindicate ligation. (8) Extreme atheroma might possibly indicate the introduction of needles, or wire, with or without galvanism. (9) Atheroma to some degree is present in the majority of arch aneurisms. (10) It is impossible technically to classify arch aneurisms. (11) The results of ligation in the case herein contained have been far more beneficial than was ever anticipated.

To Remove Obstruction from Hypodermic Needles.—Fill syringe with water, screw on needle, and place in alcohol flame at point of obstruction, using some pressure on piston. The steam generated will force out the obstruction. Useless needles can thus be made useful.

In Removing Plaster from the hands after the application of plaster casts, it would be well to remember the fact that syrup of lime is the strongest solution, and that the application of a little sugar to the hands will greatly assist you. The same rule applies to removal of casts.—*Georgia Journal of Medicine and Surgery.*

The Question of Operative Interference in Recent Simple Fractures of the Patella.—Dr. Charles A. Powers, at the meeting of the American Surgical Association, in New Orleans, April 19th, 20th, 21st, in a paper with the above title, enumerated the conditions tending to cause imperfect union and the obstacles to union as follows: (1) Separation of the fragments are due to (*a*) retraction of the upper fragment from contraction of the quadriceps femoris and a slight drawing down of the lower fragment through a shortening of the ligamentum patellæ; (*b*) effused blood. (2) Tilting of the fragments; this may be present to a marked degree and unrecognizable without operation. (3) Rupture of the tendinous expansion of the vasti and of the lateral portions of the capsule of the joint. (4) Prolapse of the prepatellar tissues into the breach. (5) Atrophy of the quadriceps femoris due to (*a*) disuse, (*b*) arthritis, (*c*) marked contusions of the muscle, (*d*) blood extravasated from the joint through a rent in the upper part of the capsule. (6) Arthritis of the knee-joint, this probably resulting in (7) adhesion of the patella. Further, though of little value, may be added (8) natural poverty of the blood supplied to the bone (rendered negative by the fact that the vertical fractures heal satisfactorily); and (9) exceptional tendency to osteitis, seen in fat people, in the aged, and in certain conditions of the blood.—*New Orleans Medical and Surgical Journal*, May, 1898.

Increase of Intradural Pressure in Head Injuries.—Dr. W. N. Bullard (*Boston Medical and Surgical Journal*, March 24th) makes the following summary: (1) An abnormal increase in the intradural pressure often occurs as an accompaniment or result of severe head injuries, when no large clot exists. (2) This intradural pressure may be in part due to an excess in the amount of subdural fluid. This, however, is, as a rule, not the chief element in the intradural pressure, which is principally due to the bulging of the brain itself. (3) The cause of this intradural pressure is apparently a congestion or filling of the intracranial blood-vessels and the results thereof.

The Surgical Treatment of Exophthalmic Goitre.—Dr. Doyen (*Rev. de Chir.*, No. 11) says there are but two operations which have the same end in view—the suppression of the secretion of this gland: (1) thyroidectomy; (2) the section of the cervical sympathetic. The methods must be judged by the results produced. One of the champions of section of the sympathetic says: "(1) Basedow's disease is modified and also cured by this operation. (2) The tachycardia is diminished and disappears after resection of the sympathetics. (3) The goitre diminishes and disappears, though somewhat more slowly than the exophthalmia."

The Other Kidney in Contemplated Nephrectomy.—Dr. G. M. Edebohls (*Annals of Surgery*, April) says that the most important resource is incision down to, delivery, and examination of the opposite kidney, previous to completing an otherwise indicated nephrectomy. He proceeds as follows: (1) The patient is placed prone upon the table. The entire width of the back is prepared aseptically. (2) An air cushion is placed beneath the abdomen. (3) A straight incision is made from the last rib to the ilium, along the outer border of the erector spinæ muscle. If the space is narrow it may be made more oblique. (4) Carry the incision through the muscles and fascia till the perirenal fat is reached. Avoid injuring the ilio-gluteal nerve; if divided, it should be sutured at the end of the operation. (5) Cut through the perirenal fat till the kidney is reached, and separate the kidney. (6) To facilitate delivery of the kidney, (*a*) if it be distended with fluid or pus, aspirate; (*b*) let an assistant draw the patient down on the table till the air cushion lies beneath the lower half of the thorax; this will cause the kidney to present at the wound. (7) Palpation of the kidney or any operative procedure necessary. If only a conservative operation is to be done, examination of the other kidney is not necessary. (8) Unless drainage of the interior of the kidney is called for, or the wound surfaces have been soiled by infectious matter, full closure of the wound without drainage should be the rule.

Dangers of Blisters.—Dr. Huchard (*Bull. de l'Acad. de Méd.*, No. 7, 1898) expresses the following opinion concerning blisters: "(1) They often produce an open wound, which facilitates secondary infections or the absorption of cantharides. (2) Besides tending to cause inflammation of the kidneys and bladder, they have a general congestive action. (3) Even in those diseases in which they are most frequently used, such as pneumonia and pleurisy, they should be discarded, because, though they increase pulmonary ventilation, they increase also pulmonary congestion. (4) Blisters tend to arrest excretion by the kidneys, so important in all infectious diseases, and this is especially harmful in those normally causing albuminuria. Instead of aiding the excretion of toxins, blisters are likely to produce a fresh intoxication. (5) The only real use of blisters is in their revulsive and analgesic action, but the effect is better attained by less dangerous means, such as mustard plasters or cold baths."

Practical Use of the Endoscope.—Dr. Herman G. Klotz (*Journal of Cutaneous and Genito-Urinary Diseases*, July) says: "The endoscope is of practical value

in three different ways: first, the determination of the nature and of the location of pathological conditions supplies, in the most exact manner, information, on the strength of which we may select those therapeutic measures which promise the best and quickest results, and apply them to the proper spot; second, by freely exposing the diseased portions to the eye and bringing them within easy reach of our hand, endoscopy naturally renders possible and invites the application of suitable drugs with great exactness to those parts, and to them only, thereby allowing the use of much stronger and more effective remedies, which would injure any but the affected portion; third, we are enabled by the endoscope to control the effects of any treatment, whether applied through the endoscope or otherwise, so that we soon can judge whether the adopted treatment is successful or not.

Therapeutic Hints.

Urticaria.—

℞ Menthol ..... 10 gm.
Chloroform ..... 30 "
Ether ..... 30 "
Spirit of camphor ..... 30 "
S. Use as a spray.

—Dr. Gaucher.

Chronic Cystitis.—

℞ Methylene blue ..... 1.6 gm.
Powd. French chalk ..... 2.4 "
Lanolin ..... q.s.
Ft. pill. No. xx. S. Two to four pills daily.

—Dr. L. Jays.

Hypodermatic Injection of Quinine.—

℞ Quinine hydrochlorate ..... 3 parts.
Antipyrin ..... 2 "
Distilled water ..... 6 "

—Laveran.

In the Catarrhal Sequelæ of Measles and Pertussis.—

℞ Creosote ..... 1 gm.
Cod-liver oil ..... 100 "
Sugar ..... 0.05 "
S. Two teaspoonfuls with the meals.

—Dr. A. Hock.

Gastritis.—

℞ Resorcin ..... 4.5 gm.
Bismuth salicylate ..... 15.5 "
Tannigen ..... 15.5 "
Powd. sugar ..... 8 "
Sodium carbonate ..... 8 "
M. S. ℥ i. q. 2 h.

—Ewald.

Painful Contusions.—

℞ Menthol ..... 3 to 6 parts.
Collodion ..... 24 "

—Néam.

Coryza.—

℞ Cocain. hydrochlor. ..... gr. iiss.
Menthol ..... gr. iv.
Acidi boracici ..... ʒ ss.
Pulv. caffeæ ..... gr. viij.
S. Use as snuff.

—Dr. H. B. Whitney.

Chapped Hands.—

℞ Tinct. benzoini co 10
Aquæ rosæ 150

Acute Purulent Otitis.—

℞ Morphinæ sulphatis ..... gr. i.
Acidi boracici ..... gr. x.
Aquæ ..... ʒ ss.
M. S. Five drops into the ear every three hours.

—Mittendorf.

Postoperative Retention of Urine.—

℞ Morphinæ sulphatis ..... gr. ¼
Quininæ sulphatis ..... gr. x.
Spir. frument ..... ʒ i.
M. S. One dose.

—T. L. Rhoads.

Or:

℞ Tinct. belladonnæ ..... ♏ xv.
Tinct. ammon. valerian ..... ʒ vi.
Sodii bromidi ..... ʒ ij.
Syr. zingiberis ..... ʒ i.
Aquæ destill ..... ʒ iij.
M. S. ʒ ii. in water every hour.

—*Jefferson Medical College Hospital.*

Epididymitis.—

℞ Pulv. opii ..... ʒ i.–ʒ ij.
Camphor ..... ʒ ss.
Vaselini seu glycerini ..... ʒ i.

—R. W. Taylor.

For Facial Neuralgia.—

℞ Tinct. aconite root,
Chloroform,
Alcohol ..... āā ʒ iv.
Oil peppermint ..... ʒ i.
M. S. Apply with a camel's-hair brush.

For the Glossitis of Alcoholics.—

℞ Chromic acid ..... gr. x.
Distilled water ..... ʒ i.
M. S. Apply lightly to points of inflammation.

Rhinitis.—

℞ Guaiacol ..... ʒ i.
Menthol ..... gr. xl.
Cocaine hydrochlorate,
Camphor ..... āā gr. xx.
Glymol ..... ʒ iv.
M. S. Use in atomizer, spraying nose and throat every three hours.

—T. T. Purkitt, *Therapeutic Gazette*, 1898.

Chronic Rhinopharyngitis.—

℞ Menthol ..... ʒ i.
Oil of sweet almonds ..... ʒ x.
M. S. Apply with a brush.

Varicose Ulcer.—

℞ Carbolic acid ..... ʒ ss.
Boric acid ..... ʒ iiss.
Camphor ..... ʒ ij.
Ichthyol ..... ʒ v.
Oil sweet almonds ..... ʒ iiss.
Zinc ointment ..... ʒ iiiss.
M. S. For external use.

Acute Pharyngitis.—

℞ Codeinæ ..... gr. v.
Extr. catechu ..... gr. xxx.
Extr. glycyrrhizæ ..... ʒ iiss.
M. ft. mass. et in trochisci No. xxx. div.

Or:

℞ Potassii chloratis ..... gr. xv.
Ol. menth. pip ..... gtt. ij.
Extr. krameriæ ..... gr. xv.
Extr. glycyrrhizæ ..... ʒ iiss.
M. ft. mass. et in trochisci No. xxx. div.

Or:

℞ Ammonii muriat ..... gr. xxx.
Pulv. ipecac ..... gr. ij.
Pulv. capsici ..... gr. ss.
Extr. glycyrrhizæ ..... ʒ iiss.
M. ft. mass. et in trochisci No. xxx. div.

The first is used in cases with moderate soreness; the second when there is cough with raw and irritable throat; the third when the secretions are thick and tenacious.—Lefferts.

Herpetic Fever (Herpetiform Pseudo-Varicella).—Paul Gastou reports several cases of herpetic fever in which the condition is not merely symptomatic, but constitutes a real disease, the fever being accompanied by an eruption of herpes which may be situated in

any part of the body. The fever lasts a few days only and is rarely higher than 102° F. There is anorexia; the tongue is saburral at the centre, red on the edges. The breath may be fetid. There is no constipation. A slight bronchitis is present. The eruptive phenomena begin to disappear on the fourth day. This disease occurs especially in young children with an arthritic heredity or subject to herpes. It is not known whether or not it is really contagious or what is its exact nature; it is more like varicella than anything else, but differs from this also in several particulars.—*Journal de Clin. et de Thér. Inf.*, March 5, 1898.

Incompatibilities.—In an article, "Ueber einige Receptsünden und ihre Folgen," in the *Berliner klinische Wochenschrift*, Professor Binz, the pharmacologist of Bonn, calls attention to the following incompatibilities: Preparations of iron with tannic acid produce ink; chloroform in glycerin or tincture of iodine in water will not mix; sulphonal is very slightly soluble in water; calomel with potassium iodide results in the formation of the irritant mercuric iodide; tincture of iodine and mercurial ointment applied locally and together produce intense irritation; permanganate of potassium added to syrups causes a brown coloration, due to the abstraction of oxygen. Combinations of explosive powders, for example, potassium chlorate and tannic acid, and also under certain circumstances combinations with permanganate of potassium, sulphur, and carbon, should not be prescribed.

For Vulvar Papilliomata.—

℞ Acidi salicylici..... 2–3.5
Collod. flexil..... 5

The method is painless; the condylomata shrivel and fall off in a few days.—Mencière, *Jour. de Méd. de Paris*, No. 6, 1897.

For Tetanus Uteri.—

℞ Tinct. iodi..... 1
Alcoholis..... 2
M. S. Five drops in a wineglassful of hot water every half-hour.

—Müller, *Allg. med. Central-Zeitung*, No. 7, 1898.

Ointment in Acute Rheumatism.—

℞ Acidi salicylici,
Olei terebinthinæ,
Lanolini.....āā 15
Axungiæ.....q.s. ad 100

The affected joint is rubbed with this ointment, covered with ordinary cotton batting, and a tight flannel bandage applied.—Sterling, *Münch. med. Wochenschrift*, No. 10, 1898.

For Leucorrhœa.—

℞ Acidi tannici..... 60
Spir. lavandulæ,
Creosoti.....āā 30
Aquæ destill..... 250
M. S. One tablespoonful in a pint of water as douche.

—Lutaud.

Iodoform Ointment for Suppurating Wounds.—

℞ Iodoformol..... 1
Balsami peruviani..... 3 gtt.
Lanolini anhydr.,
Vaselini.....āā q.s. ad 10
M. ft. ungt.

—Reuter, *Deutsche med. Wochenschrift*, No. 32, 1898.

The Prescribing of Antipyrin.—In prescribing antipyrin one must consider a number of substances with which it is incompatible. Thus, do not prescribe antipyrin in combination with substances containing nitric acid (amyl nitrite, spiritus ætheris nitrosi), inasmuch as a light green isonitroso-antipyrin is formed. With calomel antipyrin forms a very poisonous organic mercurial compound. Antipyrin and carbolic acid, even in weak solution, form a double precipitate. Antipyrin and salicylate of sodium, if mixed together in powder form, give a pasty mass. In solution, however, these two drugs are not incompatible. Antipyrin and chloral form an oily solution. With β-naphthol, antipyrin forms a moist mixture. Lastly, antipyrin increases the solubility of caffeine and quinine salts in water.—*Wiener medizinische Blätter*, May 19, 1898.

Furuncle.—

℞ Acidi carbolici..... gr. v.–x.
Extr. ergotæ fld..... ʒ i.–ʒ ij.
Pulv. amyli,
Zinc oxidi.....āā ʒ ij.
Ung. aquæ rosæ..... ʒ i.
M. ft. ungt.

—L. Duncan Bulkley.

Enteric Fever in India.—Basing his views upon an observation of forty-six cases, of which two were fatal, Dr. Quill (*The British Medical Journal*, May 14th) recommends an antiseptic treatment, having as chief constituents carbolic acid and chloroform, as in the following formula:

℞ Acidi carbolici purissimi (Calvert's No. 1) ♏ xxxvi.
Tinct. chloroformi co..... ʒ ij.
Tinct. cardamomi co..... ʒ ij.
Syrup. aurantii..... ʒ i.
Aquæ chloroformi.....q.s. ad ℥ xij.
Ft. mist. One ounce with an equal quantity of iced water to be taken every second or third hour immediately after food.

Among good effects attributed to the treatment are intellectual clearness, absence of distention, early cleaning of the tongue, lack of secondary complications, rapid convalescence.

Acute Rheumatism in Children.—

℞ Sodii salicylatis..... ʒ iss.
Potassii iodidi..... ʒ ss.
Tinct. aconiti..... gtt. x.–xv.
Aquæ..... ʒ ij.
M. S. ʒ i. t.i.d.

—Caillé.

Heart Stimulant in Catarrhal Pneumonia.—

℞ Camphoræ..... gr. iss.–iij.
Flor. benzoini..... gr. iij.
Theobromæ..... gr. vi.
M. S. Three or four times a day.

—Caillé.

Gastralgia.—

℞ Morphinæ hydrochlor..... gr. iij.
Cocainæ hydrochlor..... gr. v.–viij.
Tinct. belladonnæ..... ʒ i.–ij.
Emuls. amygd. amaræ.....q.s. ad ʒ i.
M. S. Ten to fifteen drops every hour.

—Ewald.

Threatened Abortion.—

℞ Bromide of sodium or potassium..... gr. x.
Chloral..... gr. vij.
Morphinæ..... gr. ½
M. S. One dose.

—Thomas.

Importance of Earache.—(1) Earache, however slight, may signify disease that, neglected, may terminate in loss of hearing, even of life itself. (2) Recurring earache in children is almost always associated with lymphoid hypertrophy of the pharynx, depends on it; and permanent impairment of the function of the ear is prevented only by early surgical treatment of the "adenoids." (3) Acute inflammation of the middle ear may be frequently aborted if proper treatment—mostly of a general sedative character—be administered early and with precision. (4) If relief be not obtained by the second day, an expert examination of the ear should be made, and proper

surgical treatment applied to relieve intratympanic pressure and possible involvement of the mastoid cells or intracranial structures. Failure at this stage to obtain as exact knowledge as possible of the condition of the middle ear is criminal neglect.—HINKEL, *Buffalo Medical Journal.*

Epilepsy.—

℞ Zinc oxide ..... gr. iss.
Powdered valerian..... gr. iss.
Powdered belladonna..... gr. ½
Soap ..... q.s.
M. S. Four such pills to be taken daily.

—JULES VOISIN.

Tonsillitis.—In chronic cases subject to acute exacerbations, apply directly to the inflamed area:

℞ Tinct. aconit. rad ..... ℥ ss.
Tinct. belladonnæ..... ʒ i.
Tinct. ferri chlor..... ʒ ij.
Tinct. iodi comp..... ʒ iiss.
Glycerini .....q.s. ad ℥ i.
M. S. Apply with brush.

—F. W. FABRICIUS.

Itching of Urticaria.—

℞ Distilled water..... 450 parts.
Cherry-laurel water..... 50 "
Chloral ..... 5 "
Cocaine hydrochlorate ..... 3 "

—*La Provence Médicale.*

Leucorrhœa in unmarried women:

℞ Tr. cantharidis..... ♏ xcvi.
Tr. ferri chloridi,
Acidi phosphorici diluti .....āā ♏ clx.
Syrupi limonis..... ℥ ij.
Aquæ ..... q.s. ad ʒ iv.
M. S. One teaspoonful, in water, after meals.

—SLOCUM.

Oil of Wintergreen in Rheumatism.—

℞ Ol. gaultheriæ ..... ʒ iv.
Alcoholis.
Syr. simplicis .....āā q.s. ad ℥ iv.
M. S. One teaspoonful, in Vichy, three times a day.

Bronchitis.—

℞ Codeinæ..... gr. iv.
Acidi hydrocyanici dilut..... gr. xv.
Ammonii chloridi ..... gr. xl.
Syrupi pruni virginianæ .....q.s. ad ℥ ij.
M. S. A teaspoonful every three or four hours.

—*Roosevelt Hospital.*

Malaria in Children.—

℞ Tinct. eucalypt. glob.,
Spts. vini dilut.....āā 8
Quininæ muriat..... 2
Chinoidini..... 1.25–2
Acid. mur. dil..... q.s ad solutio.
M. S. Twenty to forty drops five times a day.

—A. ZUCKERMANN.

Don'ts in the Treatment of Pneumonia.—Don't think that you can get as good results from a tub bath, or from cold general spongings, as you can from the local application of ice. Don't become alarmed when the ice produces a sudden drop in the temperature and think the patient is going into collapse. Don't fail to retain the ice as long as fever is present and resolution has not taken place. Don't omit to apply one or two ice bags to the head. Don't overlook the beneficial influence of strychnine in combating pneumonia. Administer one-twentieth of a grain by the mouth every three or four hours, and besides give the same dose hypodermically once or twice a day until the system becomes irritable. Don't omit the hypodermic injection of one-fourth of a grain of morphine once or twice a day to secure rest and sleep. Don't fail to administer oxygen by inhalation more or less constantly if the patient is cyanotic or short of breath. Don't fail to bleed if cyanosis and dyspnœa are not relieved by oxygen inhalation. Don't lose sight of the great value of tincture of capsicum in relieving great nervous depression; delirium; dry, black, coated tongue; picking at the bed clothes, etc. Give it in from a half to one teaspoonful doses in water every two or three hours, or oftener, in alcoholic pneumonia. Don't fail to give sodium salicylate, ammonium acetate, potassium acetate, and potassium citrate, three grains of each, in a dessertspoonful of peppermint water, every three or four hours, if there is the least evidence of a rheumatic complication. Don't overlook the important action of quinine in this disease. —THOMAS J. MAYO.

Snap Diagnosis.—Never make a snap diagnosis. Hasty diagnoses, like hasty marriages, will be repented at leisure.

Care in the Use of Acetanilid.—Several instances of cyanosis have recently been reported in infants from dusting acetanilid over the umbilicus. When used in these cases it should be diluted.

Tympanites.—By far the best way of relieving patients of flatus is the ordinary soap-and-water enema, with half an ounce of castor oil and half an ounce of turpentine.—DR. LOCKWOOD, *The Clinical Journal*, June 8th.

Hyperidrosis.—

℞ Ichthyol..... 25 parts.
Water ..... 15 "
Lanolin. ..... 25 "

—UNNA.

Tooth Wash.—

℞ Thymol..... 1 part.
Benzoic acid..... 12 parts.
Tincture of eucalyptus..... 60 "
Alcohol ..... 400 "
M. S. A teaspoonful to be diluted with half a wineglassful of water.

—MUELLER.

Coryza.—

℞ Subnitrate of bismuth ..... ʒ i.
Powdered camphor..... gr. x.
Powdered boric acid..... gr. xxx.
Hydrochlorate of morphine ..... gr. i.
Hydrochlorate of cocaine..... gr. i.
Powdered benzoin ..... gr. xv.
A pinch to be snuffed up the nostrils.

—*Therapeutic Gazette.*

Chalybeate Purgatives.—Dr. C. E. Williams suggests the following preparations:

℞ Ferratin,
Sodium bicarbonate.....āā ʒ ij.
Powdered rhubarb..... ʒ iv.
Oil of fennel ..... gtt. xxx.
M. S. Dose, a teaspoonful.

℞ Ferratin..... ʒ iij.
Extract of aloes..... gr. xiv.
Compound extract of rhubarb..... gr. ix.
M. Divide into thirty tablets. S. One or two to be taken twice a day.

—*New York Medical Journal.*

Follicular Pharyngitis.—Apply by means of a cotton applicator for chronic follicular pharyngitis, postnasal catarrh, and atrophic rhinitis:

℞ Iodi pur..... gr. iij.
Potass. iodidi..... gr. v.
Acidi trichloracetic..... gr. vij.
Glycerini,
Aq. dest .....āā ℥ ss.
M. This can be used in varying strengths, according to the nature of the case.

—*Tri-State Medical Journal.*

Indications for Sulphur Baths.—Dr. Partes, of Herkulesbad, gives a detailed analysis of the external and internal therapeutics of sulphur waters, and lays down the following indications for their use: (1) In

chronic catarrh of the respiratory organs, dependent more upon venous hyperæmia and unaccompanied by any special complication. (2) Circulatory disturbances in the abdomen and the gastric and intestinal disorders evoked by them. (3) Various exudative processes in joints, muscles, and bones, defective callus formation after fractures, chronic periostitis, caries and necrosis, callous ulcers, tendo-vaginitis, and deficient mobility after various injuries in which surgical interference is not indicated. (4) Chronic phlebitis, periphlebitis, and inflammations of the skin. (5) Various forms of chronic rheumatism, gout, and rheumatic and nervous paralyses. (6) Metallic poisoning, especially by lead and mercury and its after-effects. (7) Syphilis, sciatica, and neuralgia. To test the value of the sulphur treatment careful histories should be taken and the cases observed for a long period. The good and bad results should be tabulated for purposes of comparison.

Nephritis.—Dr. D. Campbell Black, of Glasgow, has used, with excellent results in fourteen cases of acute or subacute Bright's disease, a mixture made as follows:

℞ Mercury bichloride	0.06–0.2 gm.
Potassium iodide	4–12 gm.
Syrup	30 gm.
Infusion gentian	210 gm.

Dose, three tablespoonfuls daily.

This mixture appeared to relieve the renal congestion, and to bring about the gradual disappearance of the albuminuria and other symptoms of Bright's disease. —*American Medico-Surgical Bulletin.*

Pruritus of the Genital Organs.—Professor Brocq recommends the following solution for pruritus of the scrotum:

℞ Phenic acid	ʒ v.
Glycerin	ʒ iiiss.
Proof spirit	ʒ vi.
Water	ʒ x.

From one to four tablespoonfuls in a glass of hot water to bathe the parts three or four times a day, and twice a day a wafer containing sulphate of quinine and bicarbonate of sodium is swallowed. In pruritus of the vulva, Professor Tarnier prescribes:

℞ Bichloride of mercury	gr. x.
Alcohol	ʒ ss.
Rose water	ʒ v.

After washing the region with soap and tepid water the patient passes rapidly a plug of cotton wadding, steeped in the solution, over the seat of the itching. The first sensation is that of burning, but this is quickly relieved by applications of cold water. The subsequent lotions become less and less painful, and the cure is generally rapid.

A Tonic Laxative.—

℞ Ext. spigelia,	
Ext. senna	āā ʒ ij.
Ext. cascara	ʒ i.
Tr. nux vomica	ʒ i.
Tr. cinchona comp	ʒ iv.
Syr. sarsaparilla comp	q.s. ad ʒ ij.

M. S. Teaspoonful t.i.d.

—S. Henry Davis.

Bronchial Asthma.—

℞ Sodii iodidi	4 parts.
Ammon. carb	4 "
Tinct. lobeliæ	8 "
Spir. chloroformi	15 "
Vini ipecac	4 "
Infus. senegæ	q.s. ad 180 "

M. S. Tablespoonful in water every three or four hours.

—Rainear, in *Codex Medicus.*

The First Hindrance to the successful treatment of diseases of infancy is the disinclination of mothers to nurse their own children.—J. Lewis Smith.

Catarrhal Jaundice in Children.—Dr. Comby (*La Médecine Moderne*, vol. iv., p. 182) recommends the following treatment: (1) Absolute milk diet. (2) Calomel, one-sixth grain, three times a day during one week. (3) An enema every morning with warm water. (4) On discontinuing the calomel, the following powder, three times a day:

℞ Sodium bicarbonate	gr. iiss.
Calcined magnesia	gr. iiss.
Benzo-naphthol	gr. iiss.
Powdered nux vomicæ	gr. ½

Uterine Inertia.—Strychnine sulphate, one-sixtieth of a grain, thrice daily, for six or eight weeks before parturition, is a serviceable prophylactic against uterine inertia during labor.—*Canada Lancet.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CLINICAL STUDY OF FEVERS—COUNTY ASYLUMS REPORT—PHYSIOLOGICAL CONGRESS—LONDON HOSPITAL EXTENSION—TYPHOID AND BELFAST—PRINCE OF WALES—ROYAL ARMY MEDICAL CORPS—DEATHS OF DRS. WALLACE AND INKSON.

London, September 16, 1898.

In addition to the opportunities for clinical instruction mentioned in my last, the hospitals of the asylum board afford a splendid field for the study of infectious diseases. On reasonable conditions practitioners as well as students can attend these hospitals. The moderate fee of three guineas for three months and one guinea a month afterward is fixed. At the conclusion of the term one can have a certificate of attendance from the medical superintendent whose lectures and classes he has attended. The acquaintance with infectious diseases that can thus be obtained must be of the utmost value in practice, besides which a good insight into the management of fever hospitals may be obtained.

For studying small-pox, residence on board one of the ships used for these cases can be had for three or four weeks, at a charge of 12*s.* a week for apartments, board, and washing.

The annual report of the committee on asylums of the London county council shows some increase in the number of lunatics chargeable to the county and its parishes. Up to the end of March there were 1,284 lunatics residing in asylums not belonging to the council. The number treated in the county institutions reached 14,557, and the recoveries are reported to be 7.85 per cent. The pathologist, Dr. F. W. Mott, gives some interesting information in his report, especially as to general paralysis, including microscopic examinations of the brain of patients who died of this disease. He could generally find some history of syphilis. In ten cases of juvenile general paralysis he found undoubted signs of congenital syphilis in eight. He thinks syphilis the most important cause of organic disease of the brain in persons not much beyond middle life. It causes (*a*) specific arteritis, (*b*) meningitis, and (*c*) leads to the formation of gummatous growths.

The recent congress of physiologists at Cambridge was very successful. The chief object, as stated by the president, was to see actual experiments rather than receive verbal or pictorial demonstrations. Nearly one hundred communications were made. More than two hundred and thirty members attended, and sixteen foreign countries were represented. The exhibition of apparatus was scarcely so good as might have been

expected. The congress of zoölogy met the same week, numbering some four hundred members. The entertainments were shared between the two meetings, which made it easier for the hosts and more amusing for the guests.

The university conferred the honorary degree of doctor of science on Bowditch, Golgi, Kronecker, Marey, and Kühne. The vice-chancellor pronounced his Latin in the old English way, but the public orator used the continental pronunciation, and was, of course, more easily understood by foreign visitors. It is about time the English abandoned a method of pronouncing Latin which no other nation can understand, and which is destitute of all authority. Milton, who knew Latin as few now do, has set us a good example. It was agreed to hold the next meeting of the physiologists in Turin in 1901; president, Professor Mosso.

The London Hospital is again the scene of extension. A very important structural alteration is to be effected, in order to secure cross-ventilation for the two main wards. The patients will be removed to a temporary building, run up for the purpose. How this can be safely carrried out is a matter for consideration. I was talking lately with an architect who knows every foot of the building, and the conversation did not give me much satisfaction. I almost gathered that it would be better completely to rebuild than to spend nearly £100,000 on alterations and extensions. However, the decision has been taken and work begun. Four new operating-theatres are to be built at a cost of £13,000, and will no doubt be models and furnished with everything that scientific surgery suggests. In connection with the school there is to be a separate building, which will be largely devoted to Roentgen-ray work. As to the financial position of the hospital undertaking such heavy responsibilities, I may say that the press bazaar, about which I wrote some time ago, yielded a profit of £12,000, and at the quarterly court held last week it was cheering to hear that the donations amounted to £77,000 and the new annual subscriptions to £11,000. The hospital also expects £5,000 a year from the Prince of Wales' fund. This last amount is conditional on alterations, which will cost £80,000 to £90,000. It may be questioned whether the mere interest on the capital expended can be considered a good investment, especially on a security dependent on public opinion. But whether a good financial transaction or not, the alterations are needed, and will increase the usefulness as well as the prestige of the hospital. There is another source of revenue which will not do either, and may even react unfavorably. I mean the exaction of coppers from out-patients, on the pretence of partly paying for their drugs and dressings. It is an innovation which goes against the grain of almost every one, which a few years ago the staff would have opposed, but which has been carried by the committee under the influence of a zealous chairman, and is now on its trial.

The public health-committee of Belfast is making great efforts to control the outbreak of typhoid, but it looks as if it had been very negligent until lately. Typhoid is almost endemic in Belfast. The number of cases in August was seven hundred and ninety-four, but in the same month last year there were three hundred and four; yet the number of deaths from all zymotic diseases last month was twenty-five per cent. less. From the 5th inst. all drains are to be tested by inspectors before they are passed, and houses without backways are not to be built. It seems surprising that some such rules should not have been in force long ago, and their absence accounts for much of the insanitary condition of the city. Refuse destructors are also to be erected. The water is not beyond reproach, but does not appear to be the cause of the present outbreak. The new water supply is being pushed forward and will give an abundant and pure supply, but this will take time, and for the moment the insanitary state of the houses and buildings is most urgent.

The Prince of Wales' case has gone on very satisfactorily. With the apparatus to support the injured knee and one stick he can walk pretty well on level ground, and has now gone to Scotland for a change.

The royal army medical corps has done its work well in the Soudan, and this is generally recognized. Lieutenant-Colonel Sloggett, senior medical officer of the first brigade, was severely wounded in the breast in the battle before Omdurman, showing that the medical officers shared the dangers of the war in actual fighting, as was always the case.

Dr. John Wallace, consulting gynæcologist to the Liverpool Royal Infirmary, and professor of midwifery in the University College, died on the night of the 1st inst., the wedding-day of his son, Dr. Arthur J. Wallace, who is assistant professor. A large number of his colleagues attended the funeral on the 5th inst., showing the esteem in which the deceased was held. He was a pupil of Sir J. Simpson, and graduated at Edinburgh in 1861, settling at Liverpool soon afterward and devoting himself chiefly to obstetrics.

Surgeon-Major-General Inkson, M.D., died on the 9th inst., aged sixty-two years. He had medals for the Indian mutiny and the Bhootan expedition, as well as for Sweaborg.

OUR PARIS LETTER.

(From our Special Correspondent.)

LITTLE DOING IN PARIS PROFESSIONALLY—ACADEMIC YEAR SOON TO BEGIN—PROFESSORS AND PRACTITIONERS—HEALTH OF THE CITY—PROFESSOR LANCEREAUX AND TYPHOID FEVER—ITS TREATMENT BY INDICATIONS AND WAITING—PROFESSORS DIEULAFOY AND SEGOND, ETC.

PARIS, September 24, 1898.

THIS is the time of the year when there is least doing, especially in medicine. The doors of the École de Médecine are not yet open, though janitors and caretakers are cleaning up and getting everything in order for the commencement of the academic year. Those practitioners who have remained in town during the summer, either to take charge of the practices of confrères or on their own account, are now looking forward to a brief autumnal absence on the return of those whose practices they have been attending to. The majority of our professors and leading men are, however, still absent. The health of the city continues good in spite of the excessive heat that we have had. There are, of course, some cases of typhoid fever in the hospitals, as is customary in September, and of the prophylaxis and treatment of this disease Professor Lancereaux has made a long and interesting study, in which he arrives at the conclusion that the treatment of typhoid fever, to be efficacious, can only be systematic. He says very justly that in the treatment of typhoid fever, as in that of every general disease, the only rational procedure is to treat the indications. We must know how to do nothing. The best physician is the one that knows how to wait. Professor Lancereaux, in his large hospital and private experience, has found the following plan of treatment not only that which keeps down the mortality rate to the lowest possible degree, but also the one that most abridges the actual course of the disease in individual cases. During the first period he sees that the patient remains in a slight state of stupor, with a temperature of from 39° to 40° C. If this continues it is useless to intervene. In case of insomnia or intense cephalalgia, chloral, sulphonal, and opium may be given. If the

temperature rises beyond the degree named, if agitation supervenes, with or without delirium, two to three grams of antipyrin may be administered in the evening. Lukewarm baths at 28° C. and alcoholic ablutions are also very serviceable in this connection, cold baths being employed rather to calm the agitation than to lower the temperature.

Adynamia should be treated by alcoholic frictions, alcoholic drinks, tea, coffee, Hoffman's anodyne, or acetate of ammonia. If there is meteorism, which is always a bad sign, indicating a paralytic condition of the intestines, Professor Lancereaux prefers ice and cold injections to the old-fashioned remedy of a few drops of turpentine internally. Constipation he overcomes by mild saline purgatives, such as the sulphate of soda, magnesia, or mineral waters containing them, or by enemas of sulphate of soda and senna; abundant diarrhœa, by chalk, the subnitrate or the salicylates of bismuth, and charcoal. It is during the last two weeks that serious complications are most apt to occur, among the most dangerous being intestinal hemorrhages and peritonitis. In the former he advises ten drops of the perchloride of iron in an enema of one hundred and twenty grams of water, with ten drops of laudanum, or a suppository as follows: Extract of ratanhia, 1 gram; cacao butter, 3 grams. If the hemorrhages come from the smaller intestines, absolute rest should be imposed and hypodermic injections of ergotin given at once. It goes without saying that in case of peritonitis, absolute rest is a *sine qua non*, with opium in full doses, ten centigrams of thebaic extract a day, in pills of one centigram each every hour. Warm cataplasms on the stomach are preferable to ice. If the pain is excessive, a hypodermic injection of half a centigram of morphine may be given. It is during the period of the great oscillations of temperature, indicating resorption by the intestines and the fall of the "eschars," that intestinal antiseptics should be employed, one of the best being benzonaphthol. It is also during the last two weeks that grave complications may arise in the lungs, the kidneys, the liver, and the heart, which complications, like the fever itself, must be treated according to indications by cupping, ipecac, purgatives if necessary, diuretics, quinine, digitalis, and caffeine. Alcoholic patients are usually taken with delirium at the end of the disease, and with them chloral and morphine succeed best. The patient should have fresh air and clean surroundings, his bed being placed in a large, well-ventilated room, and his mouth, eyes, nose, ears, pharynx, and intestines irrigated daily. With these precautions and a good *régime* a person may, and ought to, go through typhoid fever without complications. Milk, taken every two hours in moderate quantities, is the best nourishment. Water containing some brandy and coffee may also be given. Eggs and light soups with a yellow of egg in them complete the diet. Water, especially Eau de Valz, as much as the patient likes is allowed. The above treatment of typhoid fever is one of the best, as it is one of the simplest, and is strictly in accordance with the indications, acting rather by tiding the disease over its course than by trying to check it. Germain Sée used to say, "*Respectez la fièvre*"—that is, "Let fever alone." It is only a symptom, after all, an effort of nature to throw off disease and reassert herself; but, of course, the distinguished professor had reference to only those cases in which fever was truly symptomatic—but these are very numerous.

Among our very eminent men who have already returned to Paris, I note Professor Dieulafoy, whom I met this morning dashing into the Champs Elysées behind two swift horses. Dieulafoy was practising the American habit of reading while being whirled along to his visits.

Professor Segond, the distinguished surgeon at the Salpêtrière Hospital, has been promoted to the rank of officer of the Legion of Honor. Professor Segond is well known in New York, not only professionally, but by his operative skill and writings. The promotion is a well-deserved compliment to our genial and popular confrère, who is a member of the supervising council of the Beneficiary Society, for the creation of a home for the invalids and others of the medical profession who have been obliged to abandon it. Segond's other good works are numberless.

"MOSQUITOES AND MALARIA."

To the Editor of the Medical Record.

Sir: In the Medical Record for July 30th there is an editorial on "Mosquitoes and Malaria." Possibly a statement of experience from this side of the world may throw light on the subject—or obscure it still more.

I am living in the interior of Asia Minor, on the great tableland midway between the Black Sea and the Mediterranean. The altitude of the city of Cesarea is thirty-five hundred feet above the sea. I am living five miles distant on the hills that overlook the plain, and we are five hundred feet higher. We have no mosquitoes here and we have malaria. Ten years ago this town (Talas) was considered entirely free from malaria; to-day that trouble is exceedingly common, but it has not been brought by mosquitoes. There has been no upturning of the earth, on even a small scale, for in this standstill country everything remains as it was in the days of the fathers. The soil is a thin covering over the rocks, except where there is no covering at all. The climate is dry, painfully so. There are no trees except in irrigated gardens, and as we look over the country now, there is absolutely not a green thing to be seen outside of these gardens. A part of my surgical practice consists in treating the wounds received in fights, to secure control of the small stream that supplies the irrigation.

I have made no examination of the blood for the plasmodia, but the classical symptoms and course of the disease leave no room for question of the diagnosis, and the effect of quinine and arsenic is additional evidence.

Whence comes this malaria?

William S. Dodd, M.D.

Talas, Asia Minor, August 30, 1898.

TYPHOID FEVER AND FLIES.

To the Editor of the Medical Record.

Sir: It is amazing to an old army man to see the pother that is made over the fly as a carrier of germs between the latrine and the cook-house in our military camps. Has none of these latter-day surgeons ever heard of the old-fashioned chloride of lime, and has one of them ever seen or heard of a fly that would visit a sink where the odor of chloride of lime pervaded the atmosphere?

I am told by a nurse who has just returned from Chickamauga, that when chloride of lime was asked for it was supplied in very limited quantities in little bottles, from which it had to be "poked out with a stick." When a cask of the chloride was asked for, the answer was, that it never came otherwise than in bottles.

Casks of chloride of lime containing one thousand pounds cost about $25. Ten or fifteen pounds, thrown into a latrine each day, will thoroughly disinfect the excreta, and at the same time banish every fly from the immediate vicinity.

Yours very truly,

A. H. S.

September 23, 1898.

APOMORPHINE AS AN EMETIC.

To the Editor of the Medical Record.

Sir: I am glad to see that Dr. Visanska has noticed my note on apomorphine. I am afraid that I did not make the article clear enough. One patient took two grains of morphine by mistake. I saw her an hour after. It is hardly probable that the morphine had left the stomach entirely in that time. The other case was almost similar to the first one, both as regards dose and length of time after it was taken. I think that it would be considered good practice to give an emetic under these circumstances. At that time the virtues of permanganate of potassium as an antidote to morphine were not so well known as at present, so I did not use it, but would now, of course, should I have a case. I think that apomorphine being an alkaloid of opium, and consequently related to morphine, is the reason why it would not act. Sulphate of zinc and ipecac are different bodies entirely, and perhaps have the power of exciting the vomit centre when it is deadened by opium, by stimulating it differently from apomorphine. It is difficult to produce emesis with any agent in opium poisoning, and for this reason I think it better to administer permanganate of potash as soon as possible in all such cases, because it acts as a chemical antidote, decomposing morphine. The apomorphine that I used was put up in tablet form by one of the most reliable houses in the world. For coughs, colds, and bronchitis I should think that the apomorphine treatment might be highly efficacious, but have had no experience with it in these complaints.

F. W. Van Dyke, M.D.

Grant's Pass, Oregon.

New Instruments.

A POCKET CHLOROFORM INHALER.

By J. Harris Pierpont, M.D.,

Pensacola, Fla.

The accompanying illustrations represent a pocket chloroform inhaler which I devised several years ago, and which I have since used with a great deal of satisfaction. The instrument is made of steel wire, nickeled. It is placed in an antiseptic solution before being opened. By gently pressing the upright pieces apart, they are released from the small points that hold them in place when closed, and the spring throws the side pieces into a horizontal position; two little rings which play freely on the top circle are slipped over the two projections at the upper end of the side pieces, and the frame is made steady. Then a towel is folded until its width corresponds to the height of the instrument when open, and is wrapped around the cone, one or two pins holding it in place. By unslipping these small rings and pressing the side pieces toward each other and the spiral spring downward, the instrument is closed.

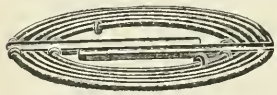

Fig. 1.—Pierpont's Chloroform Inhaler, closed.

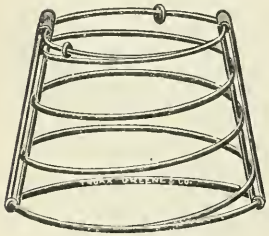

Fig. 2.—Open.

The advantages of this inhaler are that it can be carried in the coat pocket with as much ease as the hypodermic case is in the vest pocket; it allows the free entrance of air, and it permits economy in the use of chloroform, as the inhaler can be reversed when the chloroform has reached a point in the inhaler below the current of air; it cannot be made to collapse by an unruly patient, as the improvised paper ones too often can; and, finally, it may save much inconvenience and delay. It is not at all unusual to find a house without a stiff towel, or even a piece of paper to stiffen one.

I have frequently assisted in capital operations when less than an ounce of chloroform was used.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 1, 1898:

	Cases.	Deaths.
Tuberculosis	172	135
Typhoid fever	147	30
Scarlet fever	96	4
Measles	39	4
Diphtheria	113	15
Cerebro-spinal meningitis	0	7
Laryngeal diphtheria (croup)	8	7
Chicken-pox	9	0

Malarial Fever and Sea Voyage.—A sea voyage is unfavorable unless the patient is fully convalescent. H. R. H. Prince Henry of Battenberg died at sea; so did Sir William Maxwell. It is a common thing for men to come on board at Beira incompletely convalescent and die before they reach Natal. In many cases men completely convalescent succumb to the terrible black-water fever after being a few hours at sea. What the cause is, it is difficult to say. Possibly the motion of the vessel acting through the nerve centres on the vasomotor nerves of the liver may disturb its glycogenic functions, or a chill may be the cause, or it may be in the atmosphere itself. Whatever it may be, however, it is a law of malaria which it is well to bear in mind when advising a patient to take the voyage to Europe. It is too frequently the voyage from which none return.—Dr. William Forbes-Leslie, *Pacific Medical Journal.*

Artificial Legs and Arms were in use in Egypt as early as B.C. 700. They were made by the priests, who were the physicians of those early times.

A Tendency to Perspire on the slightest exertion is not infrequently coincident with habitual chilliness, and both are indicative of want of tone.

Wines and Gout.—The gout-inducing properties of certain wines are not due to their acidity. Probably these owe their action to the effect they exercise on the metabolism of the liver.—Luff.

William Harvey, Physician, of London, who, in 1616, declared that "perpetual movement of the blood in a circle is caused by the beat of the heart," is referred to by Aubrey, an English writer, in his "Brief Lives," as follows: "He was not tall; but of the lowest stature, round faced, olivaster complexion; little eie, round, very black, full of spirit; his haire was black as a raven, but quite white twenty yeares before he dyed. I have heard him say, that after his booke of the Circulation of the Blood came out, he fell mightily in his practice, and that 'twas beleeved by

the vulgar that he was crack brained; and all the physicians were against his opinion, and envyed him; many wrote against him. With much adoe at last, in about twenty or thirty yeares time, it was recieved in all the Universities in the world; and, as Mr. Hobbes sayes in his book 'De Corpore,' he is the only man, perhaps, that ever lived to see his owne doctrine established in his lifetime. He was much and often troubled with the gowte, and his way of cure was thus: he would then sitt with his legges bare, if it were frost, on the leads of Cockaine house, putt them into a payle of water, till he was almost dead with cold, and betake himselfe to his stove, and so 'twas gonne. He was hott-headed, and his thoughts working would many times keepe him from sleepinge; he told me that then his way was to rise out of his bed and walke about his chamber in his shirt till he was pretty coole, *i.e.*, till he began to have a horror, and then returne to bed, and sleepe very comfortably."

Some of the Causes of Nervous Disturbances.—But of all the cursed and damnable causes of pelvic disease and neurasthenia, the horrible means to which women resort to prevent themselves from having children must be considered. The thousand and one methods of preventing conception, the mental torture that they continually undergo for fear they will conceive, are frightful to contemplate. By and by they are perchance just as wild and crazy to have children, when all of the delicate functions participating in conception and motherhood have been so impaired, and the pelvic organs so destroyed or diseased, that conception is impossible. Then, too, there are the damnable methods of procuring abortion. I heard an explanation only recently why extra-uterine pregnancy was so common, and it was this: that the fœtus, even in its smallest form, had become shy and hid away up in the Fallopian tubes, to escape having its eyes punched out with crochet needles and septic probes of "quack" doctors.—Dr. Joseph Eastman, *Journal of the American Medical Association*, September 10, 1898.

Cocaine Habit.—A druggist in the cocaine district in Louisville, to avoid being disturbed at night, has rigged up a nickel-in-the-slot machine, it is said, which supplies a pinch of the drug to the fiends.—*Merck's Report*, August.

A Rhode Island Appetite.—In an article on "The Needs of our State Society," the editor of the *Atlantic Medical Weekly* says that among other desiderata "there should be a better discussion of papers and greater activity; there should not be so many with a reputation for wisdom gained by silence—like the young physician who saved thousands of lives by an early death. For aught we know, there may be hidden germs of future greatness in scores of our members who never open their mouths in meeting, save to eat. We need more brain work and less appetite; our meetings should not be attended by fifty and our collations by a hundred, and the subjects of discussion should be of scientific interest and not of lobster cutlets on the menu."

The Body-Physician to the Pope.—The Rome correspondent of *The Lancet* gives the following sketch of the Pope's private physician: "Giuseppe Lapponi studied medicine at the Bologna school, where he distinguished himself in the classes of Professor Concato and Professor Murri, the latter a pathologist and surgeon of high repute, and well known to the professional world as a contributor to *The Lancet*. He graduated as doctor in medicine in 1875, and after for a brief interval assisting the professor of pathological anatomy in Bologna, Dr. Tartuffi, he went into general practice, first at Capalone, in Tuscany, and next at Pollenza, near Macerata. There he remained till 1885, recommending himself by his skill, his fertility in resource, and his self-reliance, while contributing with much acceptance to medical periodicals, Italian and French. In 1888 he had transferred his *penates* and practice to Osimo, when one day he received from the Vatican an invitation to become the Pope's body-physician, the holder of that post, who had also held it in the latter years of Pio Nono, being Dr. Alessandro Ceccarelli, an excellent practitioner, who had won his fame as a surgeon and was by this time well stricken in years. Dr. Lapponi's reply was in the affirmative and he accordingly repaired to Rome, at first as assistant to Ceccarelli, who required him to pay a weekly visit to the Vatican, while still keeping a *pied à terre* at Osimo. This arrangement did not last long. Ceccarelli died and Dr. Lapponi succeeded him as physician-in-chief to His Holiness. In this position he speedily won the entire confidence of his august patient, who placed the whole management of his health unreservedly in his hands and came to consult him—as Pio Nono used to consult Ceccarelli—even on matters but remotely connected with the healing art. As years rolled by and His Holiness began more and more to feel their weight, Dr. Lapponi's attendance at the Vatican became gradually more assiduous, till of late his ordinary visits are never fewer than thrice weekly, sometimes every day, at others (when occasion requires) as often as three or four times in the twenty-four hours."

Needless Noise.—If by replacing steam with electricity on the elevated roads the nerve-destroying squeakings and gratings are going to be done away with, it will be no small blessing. How would it be for the management to order a little lubricating done in the mean time?

Some Rules for Becoming a Great Physician.—Give your opinion on everything as if you were an adept in the art, whether you understand the matter or not. Don't continue your studies, but all the more find fault with learning, journals, and bibliomania. Mention with pride the important observations and discoveries you have made to your friends often until they believe it. Be a friend of the superficial colleague, of the ministers, the druggists, barbers, and the midwives; also of the merchant, if he can be of use in attaining your purpose. Be religious and a strict observer of ecclesiastic tenets, if you can thereby add to your reputation and increase your income.—*Gruner's Almanach*, 1782.

Students are warned by Professor Orth against mere routine in their work. They should keep before them the spirit of universal medicine as an art, and educate the glance, so that the connection of the individual parts, the unity of the whole, should not be lost sight of. Above all, observation, inductive thinking, the capacity for independent research, the idea of hygiene and prophylaxis, are to be studied before commencing practice.

The Symptoms.—Fleet Surgeon: "There doesn't seem much wrong with you, my man. What's the matter?" Jack: "Well, sir, it's like this, sir. I eats well an' I drinks well an' I sleeps well, but when I sees a job of work—there, I'm all of a tremble."—*Punch.*

Internal Revenue Stamps will add to the supposed danger from the licking preliminary to the sticking process, brought up a few years ago in relation to postage stamps. The mental wear and tear of remembering to put them on at all, however, are a much more serious matter than that of any possible infection.

Headless Cigars are recommended, on the ground that they do away with the danger from the pasted end, with its possibilities for infection. Many factory operators are said to have the unhygienic and offensive habit of moistening the fingers in the mouth before making the end twist. The discovery by the San Francisco board of health of tubercle bacilli in cigars emphasizes the possible dangers.

The Communion Cup is again under discussion as a possible disseminator of germs. The question has come up in a part of California much frequented by tuberculous subjects from the East, and now even the rector of one church has raised his voice against the common cup.

The Monkey or the Penny?—In celebrating Yom Kippur a man gave a penny to the Zoo monkey named John L. Sullivan, who proceeded to swallow the same. The park veterinary who is in charge is reported in an evening paper as saying that he has "strong hopes of its recovery."

Members of the British Medical Protection Society can have their overdue accounts collected by the society. About fifty per cent. of outstanding bills, owing the members and intrusted to the society, amounting to over $100,000, have been collected in the last few years.

Care of the Water Supply in the Army of Cyrus.—A correspondent sends us the following extract from Rawlinson's translation of Herodotus, book i., § 188, published by D. Appleton & Co., New York, 1871:

"The great king [Cyrus, *circa* 550 B.C.], when he goes to the wars, is always supplied with provisions carefully prepared at home, and with cattle of his own. Water, too, from the river Choaspes, which flows by Susa, is taken with him for his drink, as that is the only water which the kings of Persia taste. Wherever he travels he is attended by a number of four-wheeled cars drawn by mules, in which the Choaspes water, ready boiled for use and stored in flagons of silver, is moved with him from place to place."

Why Teeth Decay.—The question to what extent the alkaline-earth salts in drinking-water affect the decay of teeth has of late been studied in several quarters. Statistics have been collected by Rese in several localities in Bavaria and by Foerberg in Sweden. These have revealed the interesting fact that the extent of decaying teeth bears a definite relation to the hardness of the water—in other words, to the quantity of calcium and magnesium salts in the earth through which the water passes. The harder the water the better the teeth; the smaller the quantity of these salts the greater the decay of the teeth.—*Südd. Apoth. Ztg.*

The Great Plague.—The following incident of the great plague of London is taken from an old chapbook: "During the plague carts were sent round the city each night, the drivers of which rang a bell, as intimation for every house to bring out its dead. The bodies were then thrown promiscuously into the cart, conveyed to the suburbs, and buried. A piper had his constant stand at the bottom of Holborn, near St. Andrew's Church. He became well known about the neighborhood. A certain gentleman, who never failed in his generosity to the piper, was surprised on passing one day, as usual, to miss him from his accustomed place. Upon inquiry he found that the poor man had been taken ill in consequence of a very singular accident. On the joyful occasion of the arrival of one of his countrymen from the Highlands, the piper had, in fact, made too free with the contents of the keg. These so overpowered his faculties that he stretched himself out upon the steps of the church and fell fast asleep. He was found in this situation when the dead cart went its rounds, and the carter, supposing that the man was dead, made no scruple to put his fork under the piper's belt and hoisted him into his vehicle, that our Scottish musician should share the usual brief ceremonies of interment. The piper's faithful dog protested against this seizure of his master, jumped into the cart after him, to the no small annoyance of the men, whom he would not suffer to come near the body. He further took upon himself the office of chief mourner by setting up the most lamentable howling as they passed along. The streets and roads by which they had to go being very rough, the jolting of the cart, added to the howling of the dog, had soon the effect of waking our drunken musician from his trance. It was dark, and the piper when he first recovered himself could form no idea either of his numerous companions or of his conductors. Instinctively, however, he felt for his pipes, and, playing up a merry Scotch tune, terrified in no small measure the carters, who fancied they had got a legion of ghosts in their conveyance. A little time, however, put all to rights. Lights were procured, and it turned out that the noisy corpse was the well-known living piper, who was joyfully released from his awful and perilous situation. The poor man fell badly ill after his unpleasant excursion, and was relieved during his malady by his former benefactor, who, to perpetuate the remembrance of so wonderful an escape, resolved as soon as his patient recovered to employ a sculptor to execute him in stone. The statue represents a bagpiper in a sitting posture, playing on his pipes."

Changes in the Viscera Produced by the Seventy-Two-Hours' Bicycle Ride in Paris.—At a meeting of the Academy of Science, held on August 29th, M. Regnault and M. Bianchi read a paper, in which they said that on the occasion of the recent bicycle race, which lasted for seventy-two hours, they had examined the winner, the man who came in second, and the man who came in fourth. They examined them before the race, directly after it, and during the following three days. From this examination they have drawn the following conclusions: "The riders have lost weight, and the size of the abdominal viscera—such as the spleen, the liver, and the stomach—have diminished. The subcutaneous fat has also disappeared. These changes are due to the small amount of food taken during the race, to the heat, to the want of sleep, and to the mental strain. The thoracic viscera—namely, the heart and lungs—have hardly shrunk at all, owing to the extra flow of blood through them produced by the hard work. The continual movement of the legs and of the pelvis, together with the bending forward of the body, has pushed up all the abdominal organs, and these in their turn have pushed up the heart and the lungs. The liver, as being most dense, has markedly pushed up the right lung, and the pyloric end of the stomach has been pushed up so that the organ assumes a crescent shape, and thus food stays in it for a much longer time than usual. These displacements are very marked. The abdominal organs are raised about four centimetres, and the heart is pushed up toward the neck from two to five centimetres." These facts form an explanation of the therapeutic use of the bicycle in various ptoses, pleurisy, and too straight a position of the stomach. The heart and other viscera of these three riders were extremely powerful, and so they were able to finish their ride; the other riders, who had somewhat weaker hearts, left off quite early in the race. It would therefore be advisable for race riders to be examined by a medical man, to see whether they are fit to stand the strain of long-distance rides. —*The Lancet.*

THE FUNCTIONAL NEUROSES, WITH SPECIAL REFERENCE TO NEURASTHENIA—ITS PATHOLOGY AND TREATMENT.[1]

BY A. D. ROCKWELL, M.D.,

NEW YORK.

IN no class of diseases, perhaps, are stereotyped methods of treatment—either medicinal, electrical, or hygienic—of less avail than in the functional neuroses. Every practitioner is liable to fall into certain therapeutic ruts. No one, for example, doubts the efficacy of the rest cure in many neurasthenic cases, nor can one doubt its inefficient and even injurious effects in many other cases. Neither rest, nor active exercise, nor fasting, nor stuffing can be indiscriminately prescribed, with any hope of hitting the mark except in occasional cases.

It is difficult to tell where the nervous condition ends and the toxic begins; to discriminate between cell exhaustion and the irritability that arises from the imperfectly transformed products of digestion. Close observation is required, and a careful study, not only of the present condition of the patient but of his past, his method of life, and his heredity. Various conditions, again, that we are accustomed to classify as nervous do not in reality come under that head at all, are not due to pathologic changes beginning in the nervous tissues. Hemiplegia, cerebral softening, even chorea and epilepsy in many instances do not belong to the true neuroses. The causes are mostly arterial causes. In hemiplegia, especially, it is a question of arteries, and in many choreic and epileptic cases in which the parents have had hemiplegia there is necessarily no nervous diathesis to be taken into consideration. The true unadulterated type of nervous disease is found in those conditions in which there are no arterial causes, and in which the arterial symptoms are of secondary importance and consecutive to nerve derangement.

Under this head we must class neurasthenia, in my estimation the most important of the functional neuroses, and to which I purpose mostly to confine my remarks. It is coming more and more to be understood that in dealing with this hydra-headed condition we are dealing with a derangement of cellular nutrition as positive as, and in the majority of cases perhaps more persistent than, when brought about by microbic agencies.

Neurasthenia in its more frequent aspect is simply fatigue—normal fatigue, if you will, carried to excess. Electro-physiologic experiment teaches that if either directly or indirectly we electrically excite a spinal ganglion we get a shrinkage of the nerve cells which continues for many hours, and persistent stimulation may utterly destroy the life of the cell. It is at least rational to suppose that a similar pathologic change in the nerve cell takes place under the stimulation of the varied activities of life, exhaustive mental efforts, and especially the stress and strain of abnormal emotion and early sexual abuse. Normal fatigue in these directions permits a ready recuperation; pathologic fatigue, however, does not permit a ready return of nerve and muscular tone to the normal level, and, when repeated and excessive, results in permanent exhaustion of the nerve cell. "A man is as old as his arteries," and, barring accidents, it is almost impossible for one to die whose arteries are structurally sound. He who suffers from arterial degeneration may, and usually does, live comfortably and dies suddenly, while the neurasthenic with his healthy arteries lives most uncomfortably and dies slowly. If it were not for one fortunate favoring factor, it might be a question as to the choice of these two conditions. I refer to the incurability of the one and the curability of the other.

Notwithstanding its factor of pathologic fatigue, neurasthenia does not necessarily mean mental exhaustion, for many neurasthenics are capable of sustained intellectual effort. It does not necessarily mean physical exhaustion, for many neurasthenics are equal to sustained physical exertion. It is, indeed, by no means rare to meet neurasthenics who can without distress perform unusual work of brain and body. This seeming paradox has greatly perplexed students of this disease, and more than any other fact of observation has led them to doubt the existence of any such disease as neurasthenia. That one nervously exhausted can still be equal to severe mental exertion seems to be a contradiction of terms. If, however, we take into account the reserve forces of the body, we find a partial solution of the problem.

The neurasthenic has, to be sure, but a small amount of reserve nerve force as compared with the perfectly strong and healthy man, but what reserve force there is is expended rapidly and vigorously, and results in a more effective and correspondingly larger amount of work. Profound exhaustion may result, but in the same ratio as the expenditure of force is more rapid in the weak than in the strong for the production of the same degree of profound exhaustion, so in the same ratio food and repose renew more rapidly this temporary loss of force in the neurasthenic than in the strong and healthy. This capacity for doing effective and original work on a small amount of nervous reserve force I have in my own experience seen illustrated time and time again, and the history of literature abounds in evidence that much of its best and most original production has been the work of neurasthenics. But if neurasthenia does not always mean mental and physical exhaustion, it does invariably mean a more or less profound perversion or disturbance of the *morale*, with marked psychical and sensory symptoms.

Now in these cases the question is often asked, Does electricity do good, and if so, how? The neurasthenic appears, as a rule, to be well nourished. He frequently gains weight; his color is good and his appetite often first-class. But is he well nourished? How can he be well nourished with a nervous system so erratic and unstable that the slightest influence, a casual glance even, is sufficient so to disturb the vasomotor equilibrium as to cause a general nervous disturbance, as manifested in the flushed face, perspiring hands, even dizziness and perverted vision? The neu-

[1] Read before the American Electro-Therapeutic Association, September 15, 1898.

rasthenic is not only not well nourished, in the true sense of perfect nutrition, but there is a good reason to believe that he may suffer from toxic influences, which may be both a cause and a result of the undoubted malnutrition of the nerve cells. If there is a disease more aggravating and humiliating to its victim, I have never encountered it. The symptoms are, as a rule, entirely subjective, and to those whose good opinion and sympathy the neurasthenic most covets he is too often a living lie; and in my own experience, more than one suicide has resulted, not alone because of the suffering from the disease proper, but because of the utter isolation and hopelessness entailed. The first necessary step in the process of relieving a neurasthenic is to gain his confidence, and this you can do only by recognizing his infirmities and treating them with consideration, sympathy, and respect. There is no stereotyped method of treatment. We cannot well get along without judicious medication. The weak and erratic nervous system must be temporarily sustained and soothed, while the patient is profiting by the slower process of hygiene and electricity. On some one of the various bromides, including the bromide of zinc, either alone or in combination with belladonna, cannabis indica, etc., according to individual idiosyncrasies, it has been my habit to rely more confidently than upon most other combinations. But it is to electricity that I turn for the best results that therapeutics is capable of yielding in this tedious and distressing neurosis. If it be true that neurasthenia is a disease of exhaustion, of impaired nutrition, then, theoretically, electricity ought to be of service, since as an aid to nutrition its position is sufficiently assured; and practical experience certainly teaches one that electrization is altogether the most powerful means at our command in the final restoration of perverted cellular nutrition. If I were speaking to men practically unfamiliar with electro-therapeutics, it might be expected that I would specially indicate the kind of current and the methods of application, but those who are familiar with the subject know well that this is not altogether practicable. Our experience teaches us that there is no other remedy to the effects of which there is a more varying degree of susceptibility, and especially with neurasthenics a well-kept record of cases will show a most remarkable variety of conditions. Consider, for example, the difference in susceptibility to the galvanic current. There are cases in which anything over ten or fifteen milliamperes on any part of the body seems to provoke irritability, while one-half this strength applied to the head becomes decidedly disturbing. On the other hand, there are neurasthenics whose very disease seems to make them equal to the endurance of unusual strength of current, which it is found necessary to decrease as improvement progresses.

These remarks apply to the other manifestations of electricity. It is, perhaps, hardly necessary for me to call attention to the fact that it is impossible always to predict whether it is a faradic or galvanic, static or sinusoidal form of current that will give the greatest satisfaction and the best results. The patient comes to know sometimes, far better than his physician, what agrees and what does not agree with him. If we are wise we will in these cases, like astute political leaders who "keep in the van by recognizing where the people are dimly minded to run," retain the confidence and direction of our patients by quickly divining their well-founded preferences. Among the occasional symptoms associated with the malnutrition of neurasthenia are disturbances of circulation. This instability of the circulation is more especially noticeable in the extremities; they become hot, then cold. I have seen cases in which the hands, feet, and face under emotional causes changed within a few minutes from normal to marked subnormal heat. This sudden fluctuation results in internal congestion. The kidneys especially suffer, and I have in my records a number of cases in which albumin and casts have appeared, consecutive to long-standing neurasthenia of this type. I cannot speak too highly of the action of static electricity in these conditions. The circulation is equalized, and equally as a tonic and sedative its good effects are not slow in manifesting themselves. In connection with prolonged applications of the induction current of high tension over the kidneys, I have observed in several instances the disappearance from the urine of both albumin and casts. Static electricity, together with other forms of electrization, is more than a mere tonic or sedative. They act as eliminators of poisonous principles.

Now I believe that there are forms of neurasthenia and insane conditions in which toxins may enter almost entirely as causative factors. Through poisons circulating in the blood the neurons become affected, and whether the disease is organic or functional is here, as in other conditions, the important question.

Neurasthenia is in the majority of cases functional and generally curable, while insanity is probably in the majority of cases organic, and therefore incurable. But insanity is sometimes curable, which suggests a purely functional derangement of the nerve cells, while neurasthenia may be incurable because of a chronic organic condition brought about by toxic causes. If this be true, it emphasizes the importance of early treatment.

Not only does electricity directly influence nervous action through the vasomotor system, but it excites vital function by acting directly on the cell itself and on the protoplasm, thus hastening nutritive changes and cellular activity; excretion is stimulated and poisons are eliminated. In further explanation of the *rationale* of the therapeutic action of electricity, the discovery and suggestions of M. Edouard Branly, professor of physics in the Catholic Institute of Paris, if not conclusive, are at least interesting.[1] As I have up to this time seen no English account of this discovery in physics, I may be permitted briefly to allude to it and to its possible relation to the pathology and treatment of the functional neuroses. Through no possible interpretation could it have interest for us on the old theory of the anatomical continuity of the nervous system, but in the light of the discovery of the neuron, by which we find the nerve tissue made up of distinct and disconnected elements, it immediately becomes worthy of consideration.

Briefly stated, M. Branly discovered that if a tube of iron filings be placed in a weak galvanic circuit, the meter fails to register, thus showing that the substance is practically non-conducting. If, however, the tube is previously placed in a solenoid through which course currents of high frequency, or is simply subjected to the influence of static electricity or of the cathodic ray, the tube immediately becomes a conductor and the current passes. Subject the tube with its contents, however, to some sudden shock, as that of a static spark or blow, and its conductibility is immediately annihilated.

Various theoretical considerations, unnecessary to discuss here, are advanced in explanation of these phenomena. They may or may not be the true solution of this mysterious happening, but we certainly see a similarity between the individual iron filings of the tube and the individual neurons of the nerve substance, and a striking analogy between them in their relation to electric energy and shock, which may throw light not only on the physiology but on the cause and cure of the functional neuroses. It is well known that

[1] See I.'Actualite Médicale, December 15, 1897; Archives d'Électricité Médicale, Février, 1898; Revue Internationale d'Électro-thérapie, March, April, and May, 1898.

we can hasten the recovery of hysterical paralysis by placing the patients in an electro-static field, or subjecting them to the influence of currents of high frequency coursing through a solenoid, and by other forms of electric energy. The analogy between the two—the tube of iron filings and the nerve structure—may be carried still further, since the restored nervous conductibility in a case of paralysis of hysterical origin may be instantly annihilated, as is the electric conductibility in the tube of iron filings by sudden shocks.

"Does not this help to make clear to us the characteristic causation of hysterical paralyses? Does it not reveal the traumatism which produces them? Moral or physical traumatism, emotional shock or railway accident, psychical influence or injury, brutal application of physical agents, heat, cold, light, etc.—in fact, all violent excitation is capable of producing loss of conductibility of the nerve current proper, in or through the neurons, as it can restore it when abolished."

In certain cases of hysterical paralysis patients who have been confined to bed for months or years have suddenly regained power when some violent neuromotor excitation, such, for example, as a sudden conflagration, has overcome the non-conductibility of the neuron.[1] Whether or no this discovery of M. Branly is sufficient to furnish the key, as its enthusiastic advocates suggest, to the cause and cure of the functional neuroses, it at least opens up a novel and interesting field of research.

113 West Thirty-Fourth Street.

A CASE OF SUPPURATING (STREPTOCOCCUS) PERITONITIS.

By WILLIAM R. PRYOR, M.D.,

NEW YORK.

There are three chief methods of treating streptococcus infection occurring post partum: the old one, by strychnine, alcohol, etc., which has lately been advocated; the treatment by antistreptococcus serum; and the strictly surgical treatment. Inasmuch as the matter is under consideration by a committee of the American Gynecological Society, an elaborate report may be expected in about a year; and as the surgical treatment of this form of infection will receive some attention at the hands of the committee, in all probability, it is most desirable that all cases of infection of the uterus and pelvic lymphatics by the streptococcus pyogenes be carefully reported. And while the inquiry is intended to deal chiefly with such infections occurring post partum, it is advisable to report all cases occurring after abortion or after operation. To stimulate others to make these reports, I publish the following case. Before proceeding to make a statement of X. Y——'s disease, however, I wish to request that careful notes be kept by your readers of any cases of streptococcus pelvic infection.

X. Y——, aged fifteen years, first menstruated at twelve and one-half years of age; her periods occurred every four weeks, lasted ten days, and she used thirty napkins during each period—rather generous bleeding, considering her age. She never had pain, and the blood was always fluid, never clotted. She never went to bed during her periods and never took medicines. In infancy she was both nursed and bottle-fed. She had had measles and whooping-cough, but never any lung disease. She was considered a strong child, took plenty of exercise, danced, and rode the bicycle—the latter to her ruin; but that is another story.

February 28, 1898, she menstruated. A few days later she had her first and only intercourse. She did not menstruate in March, April, May, or June.

On June 13th, she being four and one half months pregnant, an abortion was done. Apparently the means used consisted in inserting a long rubber catheter, wrapped with cotton or gauze, into the uterus. Four hours later she began to bleed, and at night her pains began. Under instructions from the midwife the patient removed the tube. The next morning the midwife removed the cotton (?). June 14th, at 11:30, the fœtus escaped and the midwife pulled out the placenta. Severe bleeding followed, but the pains stopped. On the 17th the bleeding stopped.

From the 14th to the 17th large doses of quinine had been given. During the night of June 18th she had a severe chill, and was blistered by hot applications to the belly. On the 19th "they tried to pull out something that had been left in the womb," but could not get it. This hurt the child a good deal and made her scream.

During the night of June 19th she was given chloroform and was operated upon by a doctor, who told her sister that he had removed a mass from the uterus. During the night she had a severe chill, and on the 20th she went home.

June 21st, at 10 A.M., I saw her for the first time. I found a tall, slender girl, very pale. She bore the expression of one stupid and indifferent (she was naturally bright and vivacious). Respirations shallow; pulse, 122; temperature (rectal), 102.6° F. Sordes on teeth; tongue dry, brown, and fissured. Belly drum-like and very sensitive. She vomited everything, and made silly and irrelevant remarks. Upon examination I find the vagina bathed in a yellowish discharge; there was no odor other than that of unclean genitals. The uterus was high up and fixed; no fluctuation could be felt anywhere and no inflammatory masses were detected. The corpus uteri could not be made out, it being covered by tympanitic intestines. The vaginal walls were not in apposition, but the vaginal tube was "canalized." The heart and lungs were normal. She was given a high saline enema and prepared for operation. Strychnine, gr. $\frac{1}{30}$, at noon.

Operation, June 21st, 2 P.M. Chloroform narcosis. Into the median cephalic vein I injected two pints of decinormal salt solution before beginning the operation.

Technique. Instruments were boiled for one-half hour in a five-per-cent. sodium-carbonate solution. Dressings steam sterilized, one hour at 220° F. Irrigating fluid, saturated solution of boric acid. Specimen jars boiled twenty minutes in plain water.

Personal. Soap and water. Hands and arms treated ten minutes in chloride of calcium and carbonate of sodium. Nails scraped; scrubbed for five minutes in a two-per-cent. solution of lysol; rinsed in Thiersch solution.

Uterus curetted and specimen at once placed in a sterile bottle with a glass stopper (specimen No. 1). The material removed from the uterus was broken-down decidua and shreds of uterine muscle. The organ was necrotic. I irrigated the uterus with a boric-acid solution. The bleeding was at first free but soon ceased. I packed the uterus full of gauze (iodoform) and opened the posterior cul-de-sac. At once there escaped large quantities of stinking pus. I did not measure it, but estimate the quantity to have been twelve ounces; with the pus were masses of lymph. With a piece of sterile plain gauze some pus was secured and placed in another glass-stoppered bottle (specimen No. 2). The intestines floated free in the pus. They were purple in hue, devoid of endothelium, and studded with lymph spots. They were not adherent. The broad ligaments were tense and swollen but contained no pus. The ovaries were attached

[1] M. Guimbail: Revue Internationale d'Électro-thérapie, March, April, and May, 1898.

at the pelvic brim, and were as large as eggs (acute œdematous ovaritis). The Fallopian tubes were perfectly free and the fimbriæ not occluded. I had to deal with a case of suppurative peritonitis. How far up the peritoneal sac the inflammation extended I did not, and do not, know. At no point could I see any evidence of isolation of the inflammatory process.

I shall not discuss the advisability of the method of treatment employed in this case. It is published for the purpose of putting on record a case of streptococcus infection occurring in a uterus mechanically aborted at four and one-half months, which was treated as I shall describe, the patient recovering.

Report of the Presbyterian Hospital bacteriological department on the two specimens. "Plates made from the dressing in the larger jar [specimen No. 2, intraperitoneal pus], gave an abundant growth of bacilli with a small number of colonies of streptococci. The bacilli showed the growth to be characteristic of bacilli coli communis. They produced coagulation in milk, gas, and indol. They did not liquefy gelatin. Under the microscope they were non-mobile, rather short and thick, and with rounded ends. Plates made from the gauze in the smaller jar [specimen No. 1, a mass of decidua and clot from the inside of the uterus, removed by curette before the cul-de-sac was opened] showed an almost pure growth of streptococci. The streptococci were isolated in absolutely pure culture. On the surface of agar-agar and blood serum the growth consisted of minute grayish colonies, discrete but close together, except where the surface of the culture medium was very moist. In these situations a very thin whitish layer was produced. In gelatin the growth was rather scant and did not produce liquefaction. In bouillon after twenty-four hours the liquid remained clear, with a scant whitish precipitate at the bottom of the tube. Under the microscope the growths on solid media showed rather small cocci in pairs, and short chains of four, five, and six cocci. The bouillon cultures produced chains of considerable length, up to twenty and twenty-five cocci. The tendency to form long chains is an indication of less virulence than when only short chains are formed. July 15, 1898, a guinea-pig was inoculated with a twenty-four-hours old culture in bouillon. The ear was scratched and abraded with a sterilized needle, and a drop of the culture was thoroughly rubbed into the wounded surface. Some redness and swelling developed about the wound, extending a short distance into the tissues about the ear. On the third day the animal was rather quiet and not inclined to eat, but appeared better on the following day and rapidly recovered. Inoculation from animal to animal would undoubtedly have increased the virulence of the cocci."

We have, then, produced in this case pure streptococcus infection of the inside of the uterus and streptococcus mixed with colon bacillus infection in the pelvic peritoneum. My patient's pulse twelve hours after the operation was 95; temperature, 100° F. In the six hours from midnight to 6 A.M., the vulval pads were soaked through seven times with muddy serum. The next day there were involuntary watery movements (common in streptococcus cases). At the end of the first day (after operation) the pulse was 98; temperature, 101.4° F. Thirty-six hours after operation fourteen pads had been used. Pulse, 88; temperature, 100.4° F. She was receiving $\frac{1}{100}$ gr. of strychnine hypodermically every three hours. I began to spray the nose for sordes. She got a fair amount of sleep the second night. At the time of operating I had packed the uterus with iodoform gauze, and had inserted into the pelvis nine pieces of gauze each four inches wide by one yard long—nine yards of gauze four inches wide.

June 22d, 6:30 P.M. Pulse, 100; temperature, 102° F. I removed the gauze from the uterus and washed the uterus out with a saturated solution of boric acid. The pelvic gauze was not disturbed. There were whitish patches on the cervix and the edge of the cul-de-sac incision.

June 23d, 7 A.M. Pulse, 88; temperature, 100° F.

June 25th, 10 A.M. Pulse, 84; temperature, 99.4° F. I again washed out the uterus. The gauze was all removed from the peritoneal cavity and renewed. A sample was secured under control conditions. The bacteriological report on this was: "The culture from the specimen of the 25th of June [first dressing] showed only bacilli coli communis; no streptococci were obtained."

This finding is important. I merely wish to emphasize it and at a future time will more fully discuss it. The field of surgical interference had been rendered free from pyogenic cocci.

June 27th, at 6 P.M. The pulse was 108 and temperature 102° F. In this week the girl had had twenty involuntary actions. Thirty-four gauze pads applied to the vulva, each of nine thicknesses, had been used. The discharge caught by them was greenish-brown, and frequently soaked the bedding. The pelvis was dressed as I thought best. Her general condition steadily improved; the tongue cleared, the mind improved, and vomiting ceased; the bowels were less active. Altogether she was better, except that during the second week she would occasionally develop a temperature of 103° F., which would drop to normal at times. July 3d, she was nervous all day. There was little discharge from the vagina. (I had removed all dressings.) At 8 P.M. her pulse ran from 100 at 10 A.M. to 116, and her temperature was 105° F. The cul-de-sac, which was still widely open, I packed with gauze again. In searching for a cause of the pyrexia I found a systolic murmur, heard all over the heart, not loud at the apex but increasing in intensity toward the base. I made the diagnosis of endocarditis. She received general treatment only.

On July 4th I began high enemata of decinormal salt solution.

July 5th. I have this note: "At 10 A.M., pulse, 100; temperature, 100.8° F. Discharge decreased, granulations healthy, uterus contracting."

She had her ups and downs, and on July 11th I found her at 6 P.M. with a pulse of 100; respirations, 32; temperature, 101.8° F. A swab wet in the cervical and cul-de-sac discharges was sent to the bacteriological department of the health board. I also sent a specimen of finger blood. This was the report:

"The bacteriological examination of the tubes sent from the case of X. Y——, Monday, July 11th, resulted in the finding of staphylococcus pyogenes aureus in pure cultures from the blood taken from the finger tip and a bacillus of the colon group from the culture made from the cervix. Of course this does not exclude the possibility of the case being one of streptococcus infection."

The cul-de-sac dressings were sometimes sweet and at other times stank.

July 12th, 6 P.M. Pulse, 96; respirations, 32; temperature, 100.8° F. Murmur much lessened in activity.

July 13th. Pulse, 80; temperature, 99° F. I had made repeated chest examinations and to-day got a few coarse surface râles over the back.

August 8th. Pulse, 96; temperature, 100.4° F. Systolic murmur still heard over heart, from apex to base; not transmitted to left. Liver enlarged to about twice its normal size. Spleen slightly enlarged. Abdomen flat and not sensitive to pressure. Patient fairly well nourished. Upon vaginal examination, discharge moderate; slight odor of bowel gases, not purulent. Cul-de-sac opening almost closed. Uterus and

cervix in good position but fixed. She was discharged, and went to the country.

She has reported several times, taking a railroad ride of forty miles to do so. Cheeks rosy. No pain, no fever, excellent appetite, no menstruation. Very faint apex murmur heard. Lungs normal. Cervix uteri freely movable bilaterally, but fixed posteriorly. No abdominal tenderness. Ovaries and tubes cannot be felt.

At no time during the treatment was antistreptococcus serum used. The treatment was surgical and stimulating. The endocarditis very nearly destroyed her. Although they did not show in the finger blood, I believe streptococci caused it.

A CASE OF FRACTURE DISLOCATION OF THE CERVICAL VERTEBRÆ—SEGMENTS OF VERTEBRÆ WIRED AND PRESSURE SYMPTOMS RELIEVED.

By A. V. L. BROKAW, M.D.,

ST. LOUIS, MO.

The past decade has been marked by the spirit of radicalism in all departments of surgery. While the results in the surgery of the spine are not at present calculated to arouse the enthusiasm of conservative surgeons, nevertheless occasional cases are met with in which operative efforts have been attended with success.

May 15, 1897, Drs. E. H. Higbee and E. H. Higbee, Jr., of Roodhouse, Ill., referred to me a case of fracture dislocation of the cervical vertebræ, which was of unusual interest.

The patient, an adult of slight build, marked by suffering and presenting a most distressed appearance, had met with an accident while on a hunting-trip. On October 12, 1896, he was driving to his camping-ground in a wagon, when he was apprised of a large flock of ducks flying in the direction of the road he was then travelling. Stopping his team, he stood up in the wagon and fired both barrels of his gun at the flock of ducks then immediately overhead. Losing his balance by the sudden starting of his team, he fell backward over the side of the wagon. His neck was drawn to one side and his head forced under the body of the wagon by the rapidly revolving wheels, the horses then being on the run. His companions hastened to his assistance. The patient was found lying to the side of the road unconscious. His companions, not being able to arouse him, made him as comfortable as possible and drove him home, a distance of several miles over a rough country road. Medical aid was summoned and the patient was placed in bed. His head was partially fixed by lateral supports. No attempts were made to reduce the existing cervical fracture by manipulation and extension. After a tedious convalescence of many weeks the patient was finally able to be up and about.

There were irritative cord symptoms, cutaneous numbness with shooting pains at intervals, also paralysis of the dorsal cutaneous, superficial palmar, and muscular branches of the ulnar nerve in the left forearm. There was a partial Erb's palsy, there being some loss of power of the muscles of the right arm supplied by the circumflex, suprascapular, musculo-spiral, and musculo-cutaneous nerves. Neuralgic pains of intermittent character and of severe type harassed the patient the greater part of the time when he was up and about. Considerable relief was afforded by a recumbent position with the head extended. The day of my first examination the patient was suffering no little pain. During the examination I made some traction and extension of the head, almost lifting the patient from the floor. During the manipulations the patient said, "The pain has gone out of my arm." We were assured of the correctness of the patient's statement, when on a return of the pain it was relieved by the same manipulations. The patient stated that for weeks there had been a tendency for his head to drop farther and farther forward; also that he had noted a gradual increase in the paralysis of his left arm as his head dropped farther forward. At the time of my examination the chin almost rested on the manubrium. Voluntary extension of the neck was but to a slight degree possible.

I advised an operation, to which consent was given with alacrity. The parts were carefully prepared, and on May 19, 1897, the operation was performed. The patient was placed well upon his side and anterior thorax, and an incision five inches long was made over the site of the fracture (see Fig. 1, reproduced from a skiagraph taken several days before the operation). The soft parts were deflected to either side of the spines of the vertebræ. The spine of the fourth cervical vertebra was found to have been fractured and irregularly united, the spines of the fifth and sixth

Fig. 1.

cervical vertebræ to be widely separated, the ligamentum nuchæ being completely, the ligamenta subflava partially separated. The distorsion and lateral rotation were quite marked. Not being able to correct these conditions in the position mentioned above, I had the patient brought to the end of the table and the head rotated from side to side and carried downward over the edge of the table, this latter being used as a fulcrum. The parts were then found to be in a position approaching the normal. A piece of silver wire,

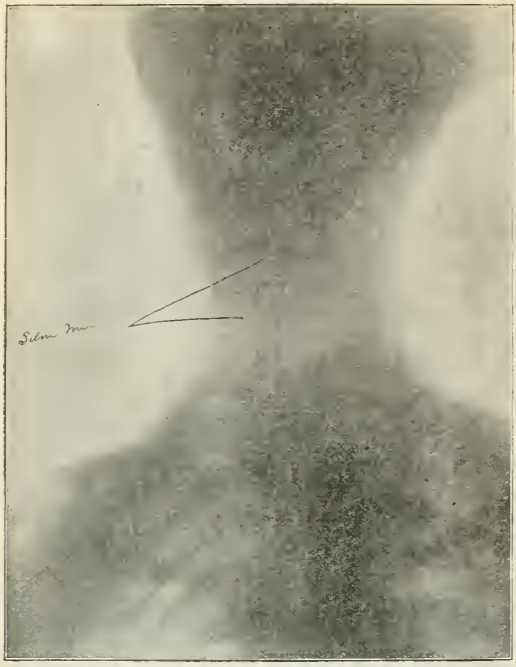

Fig. 2.

such as is used in wiring the patella and in bone resections, was carried around the spines of the vertebræ involved in the fracture, drawn taut, and twisted. Owing to the insecure attachment of the upper portion of the wire a ring of wire was passed around the spine of the third cervical vertebra and several silkworm-gut sutures were passed from one link of the wire to the other. Additional strands of kangaroo tendon were used to anchor the wires to the tendinous aponeuroses and muscles of the neck. Before the wound was closed it was noted that this arrangement of sutures maintained perfectly the desired rigidity of the several segments of the spine. The wound was closed and over the dressings were applied a helmet and cuirass of starched bandage, reinforced by strips of thick binder's board. This arrangement held the head and neck perfectly rigid.

The recovery of the patient was uneventful, without temperature rise, and free from all wound accidents. The spinal irritative symptoms and the sensory and motor disturbances were relieved, with the exception of a partial paralysis of the parts supplied by the left ulnar nerve, the functions of the little finger and the ulnar half of the ring finger being slightly impaired. Naturally there is some stiffness of the wired segments.

The patient at this time is earning his living as a house painter, and, being somewhat versatile, when not so engaged, as a well digger. Figs. 2 and 3, from skiagraphs made some weeks after the operation, show the position of the buried wires.

A feature of interest in this case is the method used in correcting the malposition of the vertebral segments by forcible manipulation. This method has recently been brought into prominence by Calot in his treatment of spinal deformities in Pott's disease.

614 North Compton Avenue.

SIX ABDOMINAL OPERATIONS.

By EDWIN M. COX, M.D.

new york.

The six cases described here are cases which I have operated upon during the past year at St. Francis' Hospital, and I have selected them for comment, because they seemed to me to have points of interest. None of them presents any great rarity, but some of the conditions were at least unusual.

Case I.—Anne R——, aged forty-eight years; admitted November 7, 1897, with a history briefly as follows: She has had a femoral hernia on the left side for a number of years, but up to the present time it has always been reducible. Five days before admission to the hospital, while the patient was doing some lifting the hernia suddenly increased in size, and became painful, tender, and irreducible. She soon began to vomit, and the vomiting became more frequent and finally stercoraceous. There was no movement from the bowels and a certain amount of tympanites developed, but when she was admitted there was no sign of general peritonitis. Her general condition was good; her pulse was 76 and her temperature 99° F. Her stomach was washed out and she was at once operated upon. The hernial sac contained about an ounce of very foul fluid and four inches of absolutely gangrenous and sloughing small intestine. This gangrenous mass was removed and the hernial ring enlarged. Then the two intestinal orifices were fixed in the

Fig. 3.

wound and a tube was introduced into the proximal end, so as to carry the intestinal contents into a convenient receptacle. There was prompt improvement in both local and general conditions, and in ten days an operation for the cure of the preternatural anus was undertaken. An incision was made along the outer border of the left rectus abdominis down to within about one inch of Poupart's ligament, and the femoral ring approached from within. With the usual precautions the two ends of small intestine were cut off as close to the ring as possible, and an end-to-end anastomosis was made by means of formalin-catgut sutures. The sections of intestine remaining fixed in the femoral ring were closed from the inside by ordinary peritoneal sutures, and then the abdominal wound was closed. Everything went well except for a little superficial infection in the abdominal wound, which necessitated a certain amount of opening and packing. On December 18th, I removed through the femoral opening the two ends of intestine, largely by a process of eversion, and allowed the wound to heal by granulation. Three months later the patient was in good health and did not suffer from any intestinal disorder. I think this is a somewhat unusual method of handling such cases, and, on account of the danger of local infection it seems safer than making an immediate anastomosis, even if we use a button or some similar contrivance.

Case II.—J. H——, aged fourteen years; admitted to hospital June 8, 1898. A week before admission the boy had a sudden attack of violent pain in the epigastrium, with vomiting and prostration, and chilly feelings. During the next day or two the vomiting ceased and there was some diarrhœa. The boy's condition became steadily worse and he was brought to the hospital. When I examined him his temperature was 102.2° F., and his pulse 130. His abdomen was much distended, tympanitic, and rigid, and there was great tenderness over the entire lower half, specially marked on the right side, where the resistance was also most marked. A diagnosis of appendicitis, with perforation and beginning general peritonitis, was made, and an operation was at once undertaken. The incision was in the usual region, and a very large amount of pus was at once disclosed. The cavity from which it came was not completely walled off from the rest of the peritoneum, and the small intestine in the neighborhood was congested and covered with lymph flakes. The end of the appendix was completely gangrenous and had sloughed away. Exploration showed that the deepest part of the cavity extended down behind the bladder, and that there was another large collection of pus, rather more completely encapsulated, extending upward alongside of the colon almost to the liver. The whole cavity was washed out with hot salt solution, and the small intestine in the neighborhood cleaned as well as possible with the same solution. The whole cavity was packed with iodoform gauze, with some strips running far over toward the left side. The boy did well for ten days, and the local conditions steadily improved. The tympanites and general tenderness soon disappeared, though for the first two days the outlook was doubtful. Eleven days after the operation there began to be evening rises of temperature and hepatic tenderness and enlargement, and on June 23d a very large abscess in the right lobe of the liver was opened and drained, four days after a preliminary incision to get adhesion with the abdominal wall. The abscess cavity was larger than a man's fist, and had very ragged walls. From this time on, the boy continuously improved and both wounds healed uneventfully. The case illustrates the occurrence of epigastric pain and iliac tenderness in appendicitis, for the latter would undoubtedly have been found if it had been sought before the boy was brought to the hospital, and thus an earlier diagnosis might have been made. A very little delay in operating would have taken away the boy's chance for life. The size of the liver abscess and the prompt recovery from it add a further element of interest to the case.

Case III.—X——, a divinity student, aged nineteen years, has had five well-marked attacks of appendicitis during the last four years, the later ones being more severe. He came for operation some weeks after the subsidence of the fifth attack. There was distinct tenderness in the iliac fossa, but no mass or resistance could be felt. McBurney's operation was done upon him on June 20, 1898, and the wound was entirely healed in seven days. The chief interest in the case was in the condition of the appendix. The organ was entirely free in the abdominal cavity. It was about four inches long and showed two tight constrictions, about one inch apart, the distal one about the same distance from the end of the organ. The end of the appendix was enlarged to the size and shape of a small olive, and when opened was found to contain about a drachm of fæcal pus. The mucous membrane was entirely destroyed, and the constriction was water-tight. Such a condition made the case one which, perhaps, in the next attack would have caused a perforation, with a condition very difficult to treat and with the probability of general peritonitis.

Case IV.—R. H——, aged seventeen years; was admitted to the hospital, July 21, 1898. His present illness began on July 13th, with gradually increasing pain and tenderness in the right iliac fossa. He had some vomiting and prostration, but no treatment up to the time of his admission. He had, on admission, a well-marked tumor in the right iliac region, extending as far as the middle line, with great tenderness all over the lower abdomen, and a temperature of 102° F. His general condition was good. He was operated upon on the day of admission, and a very large abscess found with the appendix gangrenous to within one inch of its base, and a large concretion free in the abscess cavity. The abscess extended downward and to the right, behind the bladder at its deepest part, and close to the anterior abdominal wall at its most superficial portion. It was well walled off from the rest of the abdominal cavity, and was treated by irrigation and packing. Recovery was uneventful. This case is worth comparing with Case II., and illustrates what an element of safety the formation of adhesions introduces. I might add that both this case and Case II. had symptoms of bladder irritation before operation.

Case V.—E. S——, woman, aged sixty-nine years; admitted to hospital, August 24, 1898. Patient has had a ventral hernia for twenty years but has not been troubled by it, and it has always been reducible. In January, 1898, the patient discovered a small mass in the right iliac fossa, somewhat tender on pressure but not specially painful. The condition remained about the same until three weeks before her admission to the hospital. From that time until she was admitted the mass began to increase in size and to become more painful and tender, and there was a rise of temperature from 100° to 102° F. daily. The tumor could be felt as a very painful, movable mass, about two inches long, and one in breadth, and its exact character was at first somewhat uncertain. However, it was decided that the mass was inflammatory and probably connected with the appendix, and on August 31st the patient was operated upon. A sausage-shaped mass, about four inches long and fully one inch in diameter, was found in the spot where we should expect to find the appendix, and examination showed it to be that organ. The mass was separated from its surroundings, to which it was adherent, and was cut off close to the colon, and the opening in the colon sutured in the usual way. There was very great œdema of all the tissues in the neighborhood, and a large amount of

the thickening of the appendix was due to this cause. The distal two inches of the appendix formed a comparatively thin-walled cystic structure, distended with a semitranslucent mucous material, containing bodies resembling the rice bodies found in joints. The proximal portion of the appendix was enormously enlarged and very dark in color, and the thickening was largely confined to the serous and muscular coats. A history of previous attacks of appendicitis could not be elicited. The remarkable point in this case was the enormous size of the appendix and the fact that at first the disease seems to have given very little pain, since the patient herself had noticed a mass in the abdomen, which became painful only three weeks before she came to the hospital.

Case VI.—E. G——, a rather thin woman, twenty-one years old and unmarried, came to the hospital with a history of having had a slowly growing abdominal tumor for about one year. A diagnosis of ovarian tumor, probably a dermoid, was made, and the question of operation was not at once decided, because the patient's heart action and general condition were not so good as might be wished. However, there was a sudden onset of symptoms that indicated twisting of the tumor's pedicle, and intestinal obstruction with vomiting and prostration. . As soon as possible—that is, in about twenty-four hours, the general condition being a little more favorable, and all attempts to relieve the obstruction failing, an operation was done. The tumor was found to fill the pelvis, and the small intestine in the upper part of the abdominal cavity to be much distended. It was necessary to tap the tumor with a large trocar, in order to find its pedicle. The fluid was dark fluid blood and sebaceous material. There was no trouble in tying off the pedicle, in which there were two turns, and there was no loss of blood. The uterus and other ovary were normal, and there were no evidences of peritoneal inflammation, except at the immediate front. The sudden increase in the size of the tumor, due to the twisting of the pedicle, undoubtedly accounts for the intestinal obstruction. In spite of all stimulation the patient died in about ten hours, apparently from shock and exhaustion. She had been on the operating-table about half an hour. The exhausting effects of the obstruction and the patient's poor circulation, I think, account for the failure of the operation to do any good.

SILVER AND SILVER SALTS IN SURGERY, WITH SPECIAL RELATION TO WOUND TREATMENT.[1]

By WILLIAM SEAMAN BAINBRIDGE, M.D.,

NEW YORK.

Prior to Pasteur and Lister the result of the treatment of wounds, as we all know, was shrouded in uncertainty. Pirogoff, after long experience extending over many years of active surgical practice, wrote a treatise on luck in surgery. To luck he gave the main and determining factor in the healing process. This is not strange, when we realize that in those days accurate anatomical knowledge, expert technique, and untiring attention did little to render the patient free from those deadly diseases which were then almost the rule.

The light of antisepsis soon dawned, and carbolic acid and the spray were given their places in surgery. Lister's first communication to *The Lancet* appeared in 1867, and in it he set forth his views regarding wounds as a serious complication in cases of fracture. The article begins as follows: "The frequency of disastrous consequences in compound fracture, contrasted with the complete immunity from danger to life or limb in simple fracture, is one of the most striking as well as melancholy facts in surgical practice."

From this premise the argument reaches the important conclusion that the entrance of putrefactive agents into the wound caused local and general disturbance. This naturally led to the search for antiputrefactive materials and to their use in the treatment of wounds.

"At that time," as Lord Lister said in his presidential address before the British Association in 1896, "in Scotland carbolic acid was little more than a chemical curiosity." What was true of Scotland was true of the world, but soon it became of universal use and the spray was the *vade mecum* of the surgeon.

At first the results were magnificent, and so different from those of a short time before that no material advance in new lines was made. Later air was proved to be an unimportant factor in wound disease, and the materials which came in contact with the exposed surfaces were rightly held responsible for infection. After this the spray was dispensed with and strong antiseptic solutions and dressings were solely employed.

Bacteriology now came and placed the germ theory of certain diseases upon a thoroughly scientific basis. This marked the beginning of a new era. The refined methods of Koch and others made possible the cultivation and differentiation of the micro-organisms of many of the common wound diseases. The surgeon was then permitted to see what he had believed to exist.

It was observed early in the use of carbolic acid that, while preventing disease, it was far from being free from objectionable qualities. It was irritating and toxic. The strong preparations used for irrigation and dressing had to be lessened in strength. Gradually they have been diluted, until now at times such weak solutions are used that there is apparently more effect upon the mind of the patient and conscience of the physician than upon the pathogenic bacteria themselves. Thus carbolic acid did not answer all demands for an antiseptic, and consequently many other agents appeared in an effort to supply this need. What has been true for many years is largely true to-day. The want is still unsatisfied even with the so-called classical antiseptics of the present time.

It has been the common experience of physicians to be flooded with circulars of new antiseptics. Often much of the advertising space of medical journals is occupied by announcements of "the best antiseptic." The patent-medicine man bent on personal financial gain is not the only one actively at work in this direction. Reputable chemical firms and not a few leaders in the profession here and abroad are devoting much time and thought to the subject.

The question naturally arises, What of asepsis? Has not that now come to supersede antisepsis?

A visit to a few of the principal hospitals on both sides of the Atlantic will convince one at once that there is no uniformity in the methods practised. In a clinic like that of Macewen's in Glasgow, there is strict asepsis; while in the operating-rooms of such men as Watson Cheyne and Pearce Gould, in London, strong antiseptics are liberally employed. Illustrations of the divergence in practice along this line can as well be taken from leading men of the continent of Europe and of America as from those of Great Britain. Undoubtedly asepsis holds the first place. Those who advocate the use of strong chemical agents in all cases admit that the total prevention of the entrance of germs is the ideal method, but they affirm that this is either impossible or involves too many risks. As good surgeons, on the whole, no matter what their method may be, obtain excellent results in the treatment of wounds,

[1] Read at the annual meeting of the Chautauqua County Medical Society, July, 1898.

practically the difference cannot be very great between the two extremes. Still the general consensus of opinion holds that, while at the present time there is a wise effort toward a very conservative use of antiseptics, there is a distinct field of usefulness for them.

January 25, 1896, Dr. Credé gave a lecture before the Gesellschaft für Natur- und Heilkunde, in Dresden, setting forth the claims of "Silver—Its Relation to Bacteriology and Application in Surgery." For years he had been at work searching for some better antiseptic, and in this lecture reported concerning the use of certain new agents in the treatment of wounds. The results which were then presented were further substantiated by practical and laboratory proofs embodied in a paper read at the Moscow congress, August, 1897.

The standing of Hofrath Credé and his reputation as a careful observer directed the attention of many in Germany and elsewhere and stimulated the investigation of these new preparations. With the spirit of the true scientist, he desires to have others thoroughly test what has seemed to bring such excellent results in his own hands. During a visit to Dresden in January and February of the present year, I was enabled through the courtesy of Dr. Credé and his assistants carefully to study his methods.

History of the So-Called Silver Treatment.—Dr. Credé, having seen good results obtained from the use of solutions of nitrate of silver in certain inflammatory conditions of the eye, tried this agent in the treatment of wounds. His efforts were, however, unsuccessful, because of "its ready chemical decomposition and its corrosive action." Subsequently, during a visit to America, he saw silver foil being used by Dr. Halsted in the dressing of small wounds. The effect was evident in the destruction of the micro-organisms without irritation of the tissues exposed, but no one at that time had discovered the reason for such antibacterial action. Dr. Credé noticed that metallic silver in a clean wound was not altered, but in an infected area underwent a distinct change. The next step was to understand this chemical action, and, if possible, to obtain the antiseptic material thus produced. This was done, and I cannot do better than repeat Dr. Credé's own words:

"We succeeded in determining by a series of experimental researches that the bacterial secretions acting upon silver and entering into combination with its oxides are organic acids, pre-eminently lactic acid, and that the antiseptic which an infected wound when dressed with metallic silver generates of itself is lactate of silver."

Experiments were now carried on with both the pure metallic silver and the lactate, and later with citrate of silver, a third agent which was far less soluble than the other salt.

Preparations Used.—(1) Pure metallic silver, non-irritating and possessing a distinct antibacterial action. If a Petri plate containing agar-agar be infected with staphylococci pyogenes or other germs and a small piece of silver foil be placed in the centre, a zone of considerable extent about the metal will remain free from any growth. The area of "no growth" is larger than in the case of gold or any other of the metals tested. This action of silver has led to its novel use in Dresden as a partial coating to court plaster.

(2) Solution of metallic silver. Distilled water was found to dissolve pure silver. The resultant brown fluid is not only non-irritating, but free from any toxic effect. After making a small quantity, Dr. Credé insisted upon drinking to my health some of this solution, and I, of course, returned the compliment in like manner.

Silver gauze is prepared by soaking ordinary thin muslin in a strong solution of metallic silver.

(3) Lactate of silver. A white, odorless, almost tasteless powder—unchanged when kept in a dark bottle. Soluble in 1 in 15 of water or albuminous fluid. Not irritating except on special sensitive tissues, and then in powder form. At times there may be some slight burning sensation with a strong solution. It has been proved to kill the streptococci and staphylococci in five minutes in the strength of 1 in 1,000 of water.

Catgut is prepared by Dr. Credé as follows: Having been cleansed in the ordinary way, it is soaked for a week in lactate-of-silver solution (1 in 200); then dried, and later placed in alcohol. After twenty-four hours it is ready for use. The gut is dark in color, strong, does not slip easily, and is somewhat longer in being absorbed than ordinary catgut.

Silk suturing material and rubber drainage tubes can be prepared much in the same way.

(4) Citrate of silver. Light stable powder, odorless (non-irritating), and like lactate in antiseptic power. Causes no burning sensation, and is less soluble (1 in 3,800 of water) than the other salt (1 in 15 of water). All germs ordinarily met with in connection with wounds are killed in ten minutes by an aqueous solution of 1 in 4,000. Solutions of 1 in 4,000 to 5,000 are used for irrigating wounds and body cavities. Other preparations, such as metallic and citrate of silver ointments, have been introduced and are used with promising results in certain skin diseases.

Thus I have mentioned the chief materials employed, and given a few of the results of the many bacteriological tests which have been most carefully made in the laboratory of the Carola Hospital.

Methods Used.—Perhaps I can best illustrate this treatment of wounds by briefly describing a few of the cases seen during my visit.

(1) Gastro-enterostomy — Murphy's button. The button being in place, the wound edges were thoroughly exposed and very lightly dusted with a small quantity of citrate of silver. Sutures of "silvered catgut" and "silvered silk" were introduced, all vessels having been previously tied with "silvered catgut." A small strip of silver gauze was placed over the wound and an ordinary dressing of sterilized gauze applied. Except for the use of ether and alcohol in cleansing the operating-area, no antiseptic was used on the patient or by the surgeon.

(2) Lipoma of forehead. Wound insufflated with citrate of silver and sutured with "silvered silk." A small piece of gauze was sprinkled with citrate powder and then applied to the wound. This illustrated the claim of Dr. Credé that gauze can be made as needed if no metallic-silver gauze is at hand. He goes further, and says that in an emergency the gauze need not be absolutely sterile, providing plenty of citrate be employed. I saw him use ordinary muslin fresh from the store in a number of cases without untoward results.

(3) Large alveolar abscess. A few teeth extracted and external incision made. A solution of citrate of silver freshly prepared from tablets of convenient size and strength. The solution used as a mouth wash and irrigating fluid was about 1 in 4,000. The abscess cavity was packed with metallic-silver gauze.

(4) Foreign body in knee-joint. Joint opened, foreign body removed, joint cavity washed out with citrate of silver, wound dusted and sutured. In this case, as in all the other cases mentioned, the results were excellent. There was no reactive synovitis, and healing was prompt and complete. Very many other examples might be added, but these few serve the purpose of clearly showing the methods of wound treatment which have now been used in several German hospitals for over two years.

Carola Hospital, the home of the silver treatment,

is an institution for general hospital work, having several hundred beds and only one operating-room, nineteen by twenty-one feet. Instrument and drug cases with the washing appliances take up much of the already cramped space. Considering the fact that all cases, septic or clean, undergo operation upon the same table and in the same room, the test of this new treatment is certainly most rigid. The Carola Hospital, I may also mention, has been a pioneer in other lines. Five years ago, realizing the importance of systematic physical exercise in certain cases, it led Europe in planning a specially equipped gymnasium under its roof.

Results Noticed.—On going through the wards and examining carefully the cases after operation, the results could justly be considered excellent. The following points were specially noticed: (*a*) No evidence of suture irritation. (*b*) No stitch abscesses. (*c*) No area of dermatitis about the wound, as sometimes seen with iodoform. (*d*) No systemic effect, even when the amount of the antiseptic was large.

A few practical suggestions: (1) A small quantity of the citrate is all that is required. This is important, as the salts are rather expensive. (2) Solutions must be made fresh. They are chemically changed if exposed to the light for some time. (3) It is needless to say that in testing the efficiency of these antiseptics one should be sure of his preparations. (4) No corrosion of instruments need be feared. (5) Stains produced by the solution on towels, etc., can be removed by washing, providing they have not been exposed to the light for some time.

In conclusion, I would call your attention to other fields of usefulness which appear to open up for silver salts. It seems from experiments being made that the internal administration by the stomach, and more especially by hypodermic injection, offers us a means of combating systemic infection in a way hitherto unknown. The results already secured warrant careful research in this direction, but for the final verdict we must wait further developments.

THE RELATION OF PHOSPHATURIA TO THE TREATMENT AND PROGNOSIS OF FRACTURE.

BY JOSEPH L. HOWELL, M.D.,

NEW CASTLE, PA.

MUCH has been written on the clinical value of the examination of urine and the aid it offers in diagnostic work. That it gives valuable aid to both the physician and the surgeon, in estimating the amount of elimination and metabolism, as well as in ascertaining the condition of the kidneys, the liver, the fitness of the patient to stand the administration of an anæsthetic and the shock of an operation, is unquestionable.

Aside from these conditions, it has obtained from the busy practitioner of to-day but a limited amount of practical use. There is little in the literature of the past or of the present on this subject that offers to the surgeon anything of diagnostic import, though it may be said that chemical advances in the future may reveal much more of knowledge to aid in the diagnosis of disease by perfected methods of urinary examination.

The subject of phosphaturia has been carefully studied in its relation to nervous diseases, but the widely varying results obtained by different observers leave its exact relation to such diseases far from being satisfactorily settled. The reason probably lies in the fact that the elimination of the phosphatic salts depends to a large degree upon the character of the food ingested, the variable amount of phosphates in the food, and the degree of oxidation of phosphorus in the system—which last condition depends to a large degree upon the amount of exercise, both mental and muscular, taken by the individual. It must not be forgotten also that the phosphatic salts are eliminated in the fæces and other excretions of the body. Until these difficulties can be overcome, no reliable conclusions can be made as to the exact amount of phosphates eliminated.

The aim of this article is to present a few conclusions gleaned from a careful study of the urine in a number of fracture cases. The urinary examinations were made with a view to determine the clinical value of the phosphates and the relation of the earthy to the alkaline phosphates in such conditions. It may be said, further, that these conclusions are of practical value to the surgeon in the care and treatment of such cases. They place at his disposal a test by which he can determine the condition of the bone and the extent of the reparative process. In cases of fracture, if, on examination of the urine, phosphaturia is marked, it follows that it would be unwise to allow in such a case too early use of the part, and also that more rest is indicated. In such cases the administration of hypophosphites of lime, sodium, and potassium, to aid in the formation of bone tissue, would be advisable. The study of the relations of the alkaline and earthy salts offers the most satisfactory results, as we find that in normal and healthy conditions of the body there is a definite relation between the two, the alkaline being three times the amount of the earthy phosphates. The relative value of phosphoric acid in the urine has been calculated as varying from 17 to 20; that of the blood, 3; of muscle tissue, 12.1; of brain, 44; of bone, 426 to 430.

Does not this preponderance of phosphoric acid in bone imply that its determination in all pathological conditions of bone tissue is not only of greater relative importance than in the case of nerve tissue, but also more easily arrived at?

In cases of osteomalacia examination of the urine shows a marked increase in the quantity of the lime salts, carbonates, oxalates, and especially the phosphates; this fact is supposed to be due to the reabsorption of the bone salts. In cases in which the repair of a fracture is delayed or repair does not take place properly, may it not be due to the same cause, namely, the reabsorption of the callus or the presence of an inflammatory condition in or about the callus preventing union?

The cases which are presented in the following table show the results of an examination of the urine made during the summer and fall of 1897. Twelve cases are presented, nine of them being from the surgical wards of the Buffalo General Hospital and three from the Erie County Hospital. In each case a twenty-four hours' sample was taken and a complete urinalysis made. As the examination showed no marked deviation from the normal in most of the constituents, only such items as have a bearing on our present subject are reported.

In the testing for phosphoric acid the total amount present was first computed, and then the alkaline salts were separated from the earthy.

The following solutions were used:

(1) Standard uranium-nitrate solution, 1 c.c. is equal to 0.005 gm. of phosphoric acid. This solution was first tested with a solution containing a known quantity of phosphoric acid.

(2) Sodium-acetate solution, ten-per-cent. solution of sodium acetate in ten-per-cent. acetic acid.

(3) Saturated solution of potassic ferrocyanide, used as an indicator.

Process for determining the total amount of phos-

phoric acid. Fifty cubic centimetres of urine was poured into a beaker, and five cubic centimetres of sodium-acetate solution added. The mixture was warmed over a water bath and the uranium solution added drop by drop, until the mixture gave a brown coloration when a drop of it came in contact with the potassic-ferrocyanide indicator on a white porcelain surface. The reading of the burette was then taken, each cubic centimetre of the solution used representing 0.005 gm. of phosphoric acid.

Process for determining the earthy phosphates. Two hundred cubic centimetres of urine was treated with ammonium hydrate and the precipitate allowed to stand for twelve hours; the latter was then filtered and washed with twenty-five-per-cent. ammonium hydrate; then washed into a beaker and dissolved while warm in as little acetic acid as possible. To this was added five cubic centimetres of sodium-acetate solution, made up to fifty cubic centimetres. The process was then the same as in the determination of the total phosphoric acid.

The alkaline phosphates were determined by difference.

The table shows a marked increase in the total quantity of phosphoric acid in all of the cases except two

The conclusions that may be drawn from the results of these examinations are as follows: First, that during the course of the reparative process after a fracture there is an increased elimination of phosphates amounting to a decided phosphaturia. Second, that there is a large relative increase of the earthy salts in comparison with the alkaline. Third, that as the fracture is repaired and the patient is in condition to resume free occupation this phosphaturia is less marked, and the earthy salts resume their normal relation to the alkaline.

The subject is certainly worthy of more extensive and deeper study. In so far as there has been the opportunity, a search of the literature of surgical pathology and of urinalysis has been made, and while the relation of the phosphates in certain diseases of the bones, such as osteomalacia and rickets, has been mentioned, nothing could be found on its relation to cases of fracture. As these latter are of frequent occurrence, the surgeon ought not to overlook any fact which might assist him to a better knowledge of his cases, especially in those of fracture in which for various reasons repair is delayed. His examination of the urine in such cases would be a "Roentgen ray," by which he could see the condition that existed in

(Bentley and Keeper), and in those cases the injury as regards the bone tissue was slight—in the case of Bentley the principal injury being to the spinal cord. The normal amount, according to Simon, Purdy, and other authorities, is given as ranging from three to six grams per twenty-four hours. In the cases above cited the average amount is shown to be fifteen and five-tenths grams. The significance of this increase is more notable from the fact that one of the principal factors causing the elimination of phosphoric acid—namely, exercise—is absent in these cases; the nature of the injury being of such a character as to keep the patient confined to the bed, or at least greatly limiting the amount of muscular exertion. In those cases which were examined a few days following the fracture, this increase is not so marked as in those examined at a later date, when the system was engaged in the effort of repair by the setting free and deposit of lime salts and the formation of the bony callus.

In the comparison of the alkaline and the earthy phosphates, it will be noticed that the latter are relatively increased. In normal urine the ratio between the two being one to three, the average result as shown by these cases was one to one and six-tenths, or an increase of about seventy per cent. in the earthy phosphates. The relation of the phosphoric acid to the amount of urea is of interest, in so far as it shows that the ratio between these two, which under ordinary conditions is one to seven, is changed; in some cases the amount of phosphates equals or exceeds the amount of urea eliminated.

the bone. This would be of clinical interest in deciding when a patient could walk, especially in fracture of the long bones of the lower extremity, and clinically after a patient had begun to walk, if it was thought best to allow him to do so, examination would show if there was any inflammatory trouble in the callus, indicating the need of more rest, because of softening of callus. To prevent refracture in these cases it would be well to push the administration of hypophosphites to supply bone salts, which is also true in all fractures when in depressed conditions phosphaturia is marked.

A Sign of Grave Facial Paralysis.—Drs. Bordier and Frenkel (*Le Scalpel*, June 19th) have noted a new phenomenon in peripheral facial paralysis, which has considerable prognostic value. This is the rotation of the ocular globe from above downward during the act of closing the eyelids. Bonnier says he has encountered this sign in all cases that he has observed. Frenkel and Bordier explain it as an actual nervous discharge; voluntary excitation, having no action on the facial, discharges itself in another way. Dr. Bonnier thinks that it is a simple derangement in motricity. Campos thinks that it is a physiological phenomenon becoming more manifest by the fact of a more considerable nervous impulse, and that the phenomenon is more manifest according as the impulse is more intense—that is to say, as the paralysis is more marked.

Progress of Medical Science.

Indicanuria.—Dr. Charles E. Simon, in *The American Journal of the Medical Sciences*, concludes as follows: (1) The gastric juice possesses antiseptic and germicidal properties. (2) These properties are referable to the presence of free hydrochloric acid. (3) A subnormal amount of free hydrochloric acid will call forth an increased degree of intestinal putrefaction. (4) The conjugate sulphates form an index of the degree of intestinal putrefaction. (5) The increased intestinal putrefaction in cases of subacidity and anacidity of the gastric juice is largely referable to an increased formation of indol. (6) The elimination of indican in the urine may be regarded as an index of the amount of free hydrochloric acid present. (7) A normal acidity of the gastric juice is never associated with increased indicanuria. (8) Cases of ulcer of the stomach apparently form an exception to this rule, an increased indicanuria being usually associated with hyperchlorhydria. (9) In other cases of hyperchlorhydria a subnormal or normal amount of indican is eliminated. (10) Simple constipation is rarely accompanied by an increased elimination of indican. (11) Diarrhœa referable to a catarrhal condition of the colon, often following a previously existing coprostasis, as well as diseases of the colon in general, is not associated with an increased indicanuria. (12) In the differential diagnosis between ileus and coprostasis, a small amount of indican excludes the former condition. (13) In cases of an achlorhydria with much lactic acid, the indican is not necessarily increased. (14) No indican, or but little indican, with delayed Günzburg potassium-iodide reaction, indicates the absence of free hydrochloric acid, with much lactic acid.

The Tallerman Treatment by Superheated Dry Air.—This is the new method of applying heat locally to cure disease and to relieve pains of certain arthritic diseases, such as rheumatism, gout, rheumatoid arthritis, gonorrhœal rheumatism, tuberculous inflammations of the joints; also other affections of the joints—sprains, synovitis, inflammations due to injuries; also certain affections of the nerves, as sciatica, tic douloureux and other neuralgias; also chronic ulcers, flatfoot, certain diseases of the skin, etc. In a work describing this new method, Dr. Edouard Chrétien, commenting on the cases treated at the Laennec and Salpêtrière hospitals in Paris, states the effects observed in the following terms which are fairly identical with Dr. Sibley's account, published in the London *Lancet*, August 29, 1896. (1) More or less profuse perspiration, not only of the part treated, but over the whole surface of the body. (2) Marked reddening of the skin of the part treated, indicating an intense dilatation of the blood-vessels. (3) Diminution and rapid disappearance, sometimes almost immediately, of pain. (4) Restoration of movement, when functional impotence was due only to pain. (5) More or less acceleration of pulse, caused by the peripheral dilatation of the blood-vessels, which facilitates the action of the heart, and makes it contract more vigorously.

Pregnancy Complicated by Chorea.—Dr. Dakin, in *The Practitioner* for December, in reporting seven cases in which chorea was a complication in pregnancy, draws the following conclusions: (1) Chorea is more frequent in the first than in subsequent pregnancies. (2) Legitimacy or illegitimacy is without influence upon its occurrence. (3) In the majority of cases there is a previous history of chorea or of acute rheumatism. (4) The majority of cases occur in women under twenty-five. (5) The onset of the disease is usually during the first six months, and the earlier the onset the more severe, apparently, are the symptoms. (6) In every case endocarditis (post mortem) or cardiac bruits were present. (7) In none of the cases was there any attempt at spontaneous abortion. (8) In six out of the seven cases mania occurred at some time or other, but in two the mania did not appear until after delivery. (9) In each case mania rapidly subsided after delivery, but the choreic movements were not so easily affected; in only one case did much improvement follow. This is in startling contrast with what is observed in eclampsia. In five of the cases labor was induced; in one the patient left the hospital at her own request; and in the seventh case a month's treatment with arsenic and bromides cured the chorea entirely, and the patient was discharged. (10) Chloroform is useful in quieting the spasms and inducing sleep, and should always be employed during operative manipulations. Hyoscine was also found useful. (11) Of the seven cases two were fatal, and each of these was characterized by hyperpyrexia, the temperature exceeding 106° F. (12) The prognosis depends upon the severity of the spasms, and especially upon the degree of severity attained during the first week after their onset; cases which remain mild for a week are likely to prove amenable to treatment.

The Various Methods and Indications for the Employment of Decinormal Salt Solution.—Dr. P. Findley draws the following conclusions: (1) When decinormal salt solution is indicated, enteroclysis is the method of choice, providing there is time to await its effect. (2) The body temperature, vascular tension, and renal, cutaneous, and intestinal secretions are influenced in direct ratio to the temperature of the injected fluid. (3) Injected solutions of high temperature, however, may lower the body heat by promoting the excretions. (4) A solution of 60° to 70° F. given within the colon, will first stimulate and later depress the blood tension and the secretions of the skin and kidneys. It is therefore to be used with caution, particularly in renal insufficiency. (5) In the subcutaneous method we have all that is required if immediate effect is desired, except when abdominal section may indicate intraperitoneal injections, when the withdrawal of a quantity of blood has made it possible to give intravenous injection with the least possible loss of time, and when the serous cavities have been relieved of a quantity of fluid which may be replaced by decinormal salt solution. (6) As a rule, no time is gained by the employment of the intravenous method, which should be used only when preceded by venesection for the withdrawal of blood. (7) In intravenous injections it is possible to cause death from too great dilution of the blood, an accident quite impossible in hypodermoclysis or enteroclysis. (8) Decinormal salt solution is indispensable in the treatment of alarming hemorrhage, and is of great value in the various toxæmias, and in renal insufficiency. (9) After the removal of a large quantity of fluid from the pleural cavity, the salt solution may be injected into the cavity as a substitute for the effusion, and will thereby lessen shock and relieve septic infections. (10) In cholera and cholera infantum, decinormal salt solution is invaluable as a substitute for the lost serum. (11) Venesection with the withdrawal of a quantity of toxic blood is indicated in toxæmias, when the patient is plethoric, and should be followed by intravenous injections of an equal or greater amount of decinormal salt solution. (12) In hemorrhage decinormal salt solution maintains the circulation by adding to the volume of the circulating fluid, which would otherwise stagnate in the veins, there not being a sufficient

volume for the heart to propel. (13) In toxæmias decinormal salt solution dilutes the toxins of the blood and favors their elimination by stimulating the excretory organs.—*Medical Standard.*

Coxa Vara or Deflection of the Neck of the Femur.—Dr. A. H. Tubby (*British Medical Journal*, July 23d) briefly sums the symptoms and the treatment of this condition as follows: "(1) Age: Either in infancy or adolescence; less often in childhood. (2) Class of patients: Rickety and those who carry weights and do much walking, and are subject to prolonged fatigue. (3) Onset: Peculiar stiffness of hip, spoken of as "growing" pains; the stiffness is worse on rising after sitting for a time, but is relieved by complete rest. (4) Limping, if of one side; waddling, if of both sides. (5) Shortening, amounting to as much as one and one-half inches. (6) Prominence of the trochanter, especially on flexing the thighs. (7) Displacement of the trochanter above Nélaton's line, and sometimes backward. (8) Rotation outward of the limb and eversion of the foot. (9) Limitation of inversion and final loss of abduction, with, in extreme cases, scissor-leg progression and inability to walk without crutches. (10) Tilting of the pelvis and consecutive scoliosis. (11) Signs either of infantile rickets or of late rickets, the so-called rickets of adolescence. Negatively, the absence of the following symptoms may be observed: (1) No local swelling except that presented by the displaced trochanter, and no tenderness on pressure. (2) Absence of the up-and-down movement or telescopic movement on traction of the limb so characteristic of congenital hip displacement. (3) Suppuration never occurs, nor is the thickening of the trochanter found. The treatment is simple. In the first place, in infants, rickets should be treated, and, if the disease is at all marked, it would be well to place the infant in a Hamilton or in a Bryant splint, with the legs abducted as much as possible. If there is softening of bone still present, this position will serve to lever back the head into its original position, and, if the time of softening has passed, recumbency will prevent further development of the deformity. In the case of adolescents, the first thing to insist upon is cessation of habits of long standing or the necessity of weight-bearing. Rest will then quickly relieve the pain, and the deflection of the head and neck will cease. But, if left to itself, a miserable result will follow—limping, shortening, persistent and chronic adduction of the limb, and in bilateral cases even scissor-leg deformity. If, however, the case comes to one when it is well pronounced and disability is great, I should not hesitate to recommend an osteotomy on the femur, done in one of two places, either obliquely through the great trochanter or below the trochanters. I think the best results would be obtained by the former procedure. If the patient should refuse operation, a cork sole is the only remedy."

Indication for the Use of the Double-Current Rectal Irrigator.—Dr. R. C. Kemp (*Wiener medizinische Blätter*) is credited with the following statements: "(1) The returning current provides for the elimination of flatus during irrigation. (2) The quantity of fluid necessary for irrigation is relatively small, inasmuch as we can make use of position. The principle is similar to the washing of the bladder and stomach. (3) The greater part of the work is mechanical and calls for but little exertion on the part of the patient. The fluids used are physiologic salt solution, boiled water, boric-acid solution, salt solution with a few drops of peppermint oil, permanganate of potassium, bichloride (1–10,000). Irrigation is to be performed but once daily, and never more than three days in succession. The amount of fluid to be used depends upon the case at hand. The conditions in which this method was employed were catarrhal colitis, membranous or croupous colitis, acute and chronic dysentery, gastro-enteritis of children, amœbic dysentery, typhoid fever, chronic constipation, intestinal paralysis, duodenal icterus, as well as shock, uræmia, and hemorrhagic anæmia."

Epilepsy.—Dr. Hermann Beer (*Klin.-therapeut. Wochenschrift*, September 11th) divides the subject as follows: *A*. Genuine epilepsy. Epileptic attacks without apparent cause. *B*. Symptomatic epilepsy. (1) Intoxication epilepsy. Alcohol, lead, carbon dioxide, ergotin, antipyrin, arthritis (urea), nephritis (urea), intestinal sepsis. (2) Infectious epilepsy. Syphilis, cholera, variola, morbilli, sepsis. (3) Diseases of the brain. Emboli, apoplexy, tumors, multiple sclerosis, hyperæmia. (4) Reflex epilepsy. Masturbation, menstruation, pregnancy, constipation, intestinal parasites, dilatation of the stomach, cicatrices, thrombosis in the external auditory canal or in the Eustachian tubes. (5) Traumatic epilepsy. Injuries of the head. (6) Cardiac epilepsy. (7) Physical and mental overexertion, irregular mode of living, worry, and depression of spirits.

Widal's Reaction in the Diagnosis of Typhoid Fever.—Dr. Schabad, of Wilna (*Medisinskoye Obosrenye*), as a result of extensive hospital experience draws the following conclusions: (1) In the hands of an expert and with an active culture the Widal reaction is a very useful aid in the diagnosis or exclusion of abdominal typhus. (2) A marked or medium positive reaction, which is seen microscopically with a 1 in 50 dilution, speaks for typhoid fever, a medium and absolutely negative one against the disease. The macroscopic negative reaction does not, however, exclude typhoid. (3) The severity of the disease at times influences the intensity of the reaction, but particularly the duration of the same. (4) The positive reaction may appear five or six days after the beginning of the disease and may exist one year after convalescence. (5) Instead of using blood and blood serum, the same results may be obtained by using the serous exudation from bullæ. (6) The examination of the urine, in accordance with the principle of Widal, does not give satisfactory results. (7) For diagnostic purposes formalin cultures may be used in place of fresh ones. (8) The existence of unclassified forms of typhoid must be looked upon as doubtful. There are, in all likelihood, infectious diseases which run a course similar to typhoid, the nature of which is as yet not thoroughly understood.

A New Pulse Phenomenon in Neurasthenia.—Erben (*Wiener klinische Wochenschrift*, 1898, No. 24) describes a pulse phenomenon in neurasthenia, which has thus far not been mentioned. If the patient bends forward or makes an attempt to sit down, a distinct and easily appreciable slowing of the pulse takes place, which, however, returns to normal in a very short time, whether the patient assumes the erect position or not. Even neurasthenics with tachycardia show the phenomenon. Healthy individuals do not show this phenomenon, which Erben attributes to vagus irritation. In tachycardia dependent on other conditions this phenomenon does not occur, so that the author places great stress upon its differential value.

The Therapeutic Uses of Iodine, and the Choice of its Combination with Sodium or Potassium.—Briquet (*La Presse Médicale*, 1898, No. 5) makes the following statements: "(1) Iodine is of use in the majority of cases of arterio-sclerosis, aneurism, acute and chronic aortitis, and in the circulatory disturbances of some cases of uncompensated heart lesions. Among

affections of the respiratory apparatus it is especially indicated in true asthma, in prolonged influenza bronchitis, in some cases of acute as well as in dry chronic bronchitis, in chronic pneumonia, pulmonary congestion, and in chronic coryza and ozæna. Among the infectious and parasitic diseases it is of great value in syphilis and actinomycosis. It is of further service in mercurial and chronic lead poisoning, of occasional good in some arthritic affections, hyperostoses, and iritis. On the other hand, iodine is useless in affections of the digestive tract, liver, and kidney. It is also of no value in non-syphilitic disease of the nervous system or in the infectious diseases. Contrary to the generally accepted belief, it is also useless in its effect upon the secretion of milk. (2) Generally speaking, iodide of potassium is preferable to the iodide of sodium, except in disease of the respiratory apparatus and in some cases of rheumatic pains. If the iodide of potassium is badly borne at the beginning or during the course of treatment, replace it by the sodium iodide, which is but slightly inferior to the potassium salts in its therapeutic effect. At the beginning of medication it is advisable to use the sodium iodide, because it is better borne, as a rule. When the organism has become accustomed to the iodine, then the potassium iodide may be used. If used for a long time, iodide of potassium seems to act as a depressant. Therefore, if the iodine treatment is to be kept up for any length of time, it is advisable to alternate both salts."

Innervation of the Heart.—Professor v. Leyden at the Verein für innere Medicin in Berlin (*Münchener medicinische Wochenschrift*, July 12th) made the following statements: "(1) The heart of the embryo pulsates long before it is possible to demonstrate any nerves therein. (2) There exists unstriped muscle, in which neither nerves nor ganglion cells can be demonstrated, and in which contraction still occurs, viz., the ureters. (3) The experiments of His and others have shown that the cardiac nerves originate in the sympathetic and only gradually enter the heart; the heart ganglia originate from the spinal ganglia, which are purely sensory. Therefore the cardiac nerves are also of a sensory character, and for that reason unable to send forth motor impulses. (4) Finally, in no part of the heart have nerve endings of the character of a motor end apparatus been demonstrated."

Therapy of Lipomatosis Universalis.—Dr. E. H. Kisch (*Wiener med. Presse*, 1898, No. 11) gives the following directions: (1) Diminish the amount of food. The necessary amount of food stuff for an extremely stout person is one-fourth less than in an equally heavy normal individual. (2) Proteids must be taken in abundance, carbohydrates to a moderate degree, fats in a minimal amount. (3) Fluids (with the exception of alcohol) are not to be diminished except during meals. Only in cases of cardiac insufficiency are large amounts of water contraindicated. (4) Systematic bodily movements are advisable, except in anæmic individuals. (5) Diminish the hours of sleep and forbid sleeping during the day. (6) Increase the excretions by means of baths and fresh air.

Methyl Salicylate in Acute Articular Rheumatism.—Molteni, after a thorough trial of this drug, concludes as follows: (1) In sciatica the result was always satisfactory. (2) In chronic articular rheumatism the results were such that we can look upon this drug as the best known therapeutic agent of the present day. (3) In acute febrile articular rheumatism methyl salicylate proved useless in children, and of slight value in adults. Still the drug lessened the local pain. (4) In arthritis of the vertebral column it proved of no value in old cases, but very good in fresh cases. In sero-fibrinous pleurisy it gave excellent results. The method of application consisted in pencilling the affected region once daily with equal parts of olive oil and methyl salicylate.—*Wiener medizinische Blätter*, August 11, 1898.

Cystitis and Pyelitis: Differentiation.—Dr. George Rosenfeld concludes as follows: (1) An alkaline reaction of the urine is not found in uncomplicated cases of pyelitis. (2) The border line of the maximum amount of albumin in cystitis is from 0.1 to 0.15 per cent. (3) If most of the pus cells are irregularly contorted, the case is probably one of pyelitis. (4) If the existing red blood cells are for the most part chemically or morphologically destroyed, it speaks—if the hemorrhage be microscopic and in the absence of tumor of the bladder—for pyelitis.—*Wiener klinische Rundschau*, September 11, 1898.

Predisposing and Etiological Factors in Infantile Spastic Hemiplegia.—König (*Allgemeine medicinische Central-Zeitung*, July 2d) concludes as follows: "(1) We know of but three etiological factors in the causation of the cerebral hemiplegia of children: (*a*) severe labors, especially if the child is born in a state of asphyxia; (*b*) trauma of the head; (*c*) the infectious diseases. (2) All other factors can be looked upon as predisposing agents, according to our present knowledge. Of course the possibility of these becoming etiological factors is not altogether excluded. (3) The difficult labor as well as the asphyxia and head trauma may under certain circumstances act as predisposing agents. (4) In those cases with an etiology we often meet with predisposing factors. (5) In the vast majority of cases in which an accurate history can be obtained, numerous predisposing conditions can be found. (6) The traumatic infantile hemiplegia cannot at present be placed in a separate category. (7) The psycho-neurotic heredity as well as alcoholism of the parents occupies a prominent place among the predisposing causes. (8) The existence of family cachexia is of still greater significance. (9) Phthisis seems to exert a certain predisposing influence upon the condition. (10) Syphilis occupies only a secondary position."

Vaginal Hysterectomy.—Dr. Friedrich Schauta, in his book, "Lehrbuch der gesammten Gynäkologie," states that he performs total vaginal extirpation of the uterus in the following conditions: (1) In carcinoma or sarcoma of the cervix or body of the uterus if the carcinoma is limited to the uterus or its immediate neighborhood. (2) In myoma of the size of a child's head, provided the uterus is freely movable. (3) In total prolapse of old women with atrophy of the pelvic floor, marked hypertrophy of the uterus, when a plastic operation does not offer any hope of success and when treatment with pessaries has proven useless. (4) In inflammatory conditions of the adnexa, when the marked discomfort cannot be relieved by means other than operation. (5) In chronic inflammation of the uterus and endometrium, when repeated therapeutic measures, particularly curettage, have proven useless, and when dangerous hemorrhage repeatedly occurs. (6) In severe atonic hemorrhage during the puerperium, as well as in rupture of the uterus in exceptional cases.—*Deutsche Medizinal-Zeitung*, August 29, 1898.

On Poisoning by Coal Gas.—Dr. G. Cruz (*Ann. d'Hygiène Publique*, May, 1898) believes that it is possible to differentiate those cases of poisoning in which coal gas has been directly inhaled from those due to the inhalation of the products of incomplete combustion. In experimenting upon animals he has found that the blood of those poisoned by coal gas always

contains minute traces of hydrocarbon, while that of animals poisoned by the products of incomplete combustion (coal, wood, anthracite) did not show the faintest trace of hydrocarbon. On account of the infinitesimal quantity, the writer has been unable to determine the form in which the hydrocarbons existed. Their presence was determined by the following method: With an air pump the hydrocarbons were exhausted from the blood; then by means of an electric spark passed through the exhauster they were converted into acetylene. An ammoniacal solution of chloride of copper was then employed to develop the typical reaction. If this method is to be relied upon, it will prove of great value in forensic medicine.

Rectal Administration of Salicylate of Sodium in Rheumatism.—Dr. Harlet, of Roubaix (*Klinisch-therapeutische Wochenschrift*, No. 32, 1898), asserts that rectal administration possesses the advantage of more rapidly relieving the pain; heart complications and relapses are avoided, and the digestion is not disturbed. He orders from eight to twelve grams of sodium salicylate daily, in two clysters, to which a few drops of laudanum are added. The rectum is previously irrigated. The drug is absorbed in from six to eight hours. Every second day the dose of salicylate is diminished by one gram until the daily dose is seven grams, when but one clyster is given. Tinnitus aurium seldom results and vomiting rarely occurs. The method gives good results, not only in acute rheumatism but also in the subacute form, in gonorrhœal arthritis, in rheumatic iritis, and in pleuritis *a frigore*.

On the Origin of Post-Mortem Ecchymoses.—*Treatment*, part i., July 14, 1898, reviews an interesting article of Dr. Albin Haberder (*Viertelj. f. ger. Med.*, April, 1898). The late Professor von Hofmann, of Vienna, was the first to draw attention to the important fact that in dead bodies not only may ecchymoses become more extensive, owing to hypostatic congestion, but capillaries may even burst, and thus produce hemorrhages which differ in nothing from those petechial hemorrhages which occur during life. When bodies, twenty-four to forty-eight hours after death, were suspended, it was possible to produce extreme degrees of hypostatic congestion, but no ecchymoses; but if bodies were suspended a short time after death, the results obtained were as follows: In all the bodies of seven newly born infants which were suspended shortly after death, small punctiform or streaky hemorrhages were produced in the conjunctiva of the eyeball in from a few to twenty-four hours after suspension, which could not be distinguished from ordinary ecchymoses which had been produced during life. It was also possible to watch the gradual enlargement of these hemorrhages; in some instances small petechiæ were produced, even in the cortex of the hemispheres of the brain over the convexity, which looked like those produced by commotion or capillary embolism. . . . Before suspension there was not the slightest evidence of conjunctival hemorrhages, even in examination with a magnifying lens. . . . It is not a rare thing to find numerous petechiæ in the skin over the chest or abdomen, the shoulders, arms, neck, and face of bodies of people who have been found dead, lying in bed with the upper part of the body hanging out over the edge of the bed. . . . But it is not necessary that the bodies should be found in a dependent position; even those which are stretched out horizontally on their back show sometimes—especially when their blood remains liquid for a long time—quite a number of petechiæ on the back and the lateral sides of the chest and abdomen. The fact that these petechiæ are more often found in old people justifies the supposition that the greater vulnerability of the walls of the capillaries in old people predisposes their bodies to ecchymoses of this kind. Occasionally these ecchymoses are found in the bodies of persons who died from prussic-acid poisoning, and in children who have been suffering from rickets or acute and chronic gastro-enteritis. It is quite possible that the origin of these post-mortem petechiæ is to be sought in minute capillary hemorrhages which occur in the agonal stage, and become visible only after death, owing to hypostatic oozing of blood from minute rents in the capillary walls. The differential diagnosis between post-mortem ecchymoses and those produced during life is very difficult as long as the hemorrhage is only small. Theoretically, one might say that in intra-vitam hemorrhages the blood ought to be coagulated; but we know now that the blood retains its coagulability for some hours after death; and if, as is often the case, a post-mortem hemorrhage takes place between muscle fibres, it may be impossible to remove it thence with water. But when one finds on cutting into an ecchymosis that the blood flows out by itself or on gentle pressure, then it is clear beyond doubt that the ecchymosis has occurred after death. . . . During life ecchymoses are much more frequently observed in children than in adults. The same seems to hold good also as regards post-mortem ecchymoses in internal organs, whereas cutaneous ecchymoses are more frequent in adults than in children. It cannot be doubted that occasionally ecchymoses are formed in the lungs, the heart, and the thymus in consequence of the pressure of the blood, which, following the law of gravitation, after death is collected in the dependent parts of the body; but it must also be remembered that in many instances minute lesions may have occurred in the walls of capillaries during the agonal stage, which, after death, become larger, and therefore visible to the naked eye. Nothing could be more injudicious than to diagnosticate death from suffocation because a few ecchymoses have occurred under the pleura or the pericardium of children who have been found dead in bed. Such ecchymoses are of diagnostic value only when they appear in parts where there is not, and never has been, any hypostatic congestion, when there are signs of hyperæmia and congestion which have existed during life, and when infectious and septic diseases, diseases of the blood and indications of poisoning can be absolutely excluded.

The Chemical Relations of Remedies in Scientific Therapeutics.—Dr. John V. Shoemaker (*Journal of the American Medical Association*, September 24th) says: "As the active principles of all plants have not yet been isolated, it need be no wonder that in a new field, and dealing with complex animal tissues, this problem, for most substances, remains unsolved. A beginning, however, has been made. The efficacy of orchitic extract depends upon the presence of an organic crystalline substance called spermin, which exists in combination with hydrochloric acid. The active principle of the thyroid gland is believed to be the substance isolated under the name of iodothyrin. In the same way the antitoxins, in so far as they have been discovered, may be looked upon as the active principles of the immunizing or curative serums. Schaefer and Oliver have obtained from the medullary portion of the suprarenal bodies an organic principle which has a powerful action upon the heart, voluntary muscles, and peripheral arteries. The serums obtained from animals rendered artificially immune contain antitoxins, and have proved of more value than those from animals naturally immune to certain maladies. The typical instance of success in this form of therapy is diphtheria antitoxin. The wonderful reduction in the mortality from diphtheria which this

preparation has effected cannot be gainsaid. Every physician should seriously debate in his own mind whether he has done his duty in a case of diphtheria, if he has neglected to take advantage of the immunizing properties of diphtheria antitoxin."

How to Diagnosticate a Movable Kidney.—Dr. C. W. Suckling, in an article entitled "On Movable Kidney, with Special Reference to its Influence on the Nervous System" (*Edinburgh Medical Journal*, September), says: "The diagnosis can be made only by palpation of the abdomen, the patient lying down. To feel the right kidney the right hand should be placed on the abdomen, the thumb being on the last rib at the back and the fingers in front below the costal margin. The kidney may be felt with slight pressure of the fingers if it is pressed down, but if not, when the patient draws a deep breath, the kidney will slip into the fingers and can be slipped back easily. A common mistake is to palpate the abdomen with the flat of the hand; this simply pushes the kidney in front of the hand. The best way is to get the kidney between the thumb and fingers, and not to press too heavily, so that the kidney cannot come down. When the patient assumes the sitting or standing position, the kidney comes down more than it does during inspiration when he is lying down, and it is necessary, before concluding that the kidney is not movable, to examine the patient sitting or standing. In these two positions the patient should lean forward and try to relax the muscles. To illustrate the importance of this, two years ago I sent to a surgeon to be operated upon a woman who had a movable kidney and was unable to do her work. The surgeon could not find the kidney when she was put under the anæsthetic. He sent for me the following day to examine the patient again. I could not find the kidney while she was lying upon her back, but when she sat up the kidney could at once be felt in the right iliac fossa. In examining the left kidney the left arm should be placed around the body, the physician standing on the right side of the patient, the fingers being placed under the last rib; the right hand should be placed under the left costal margin. On drawing the breath or on sitting or standing, if the kidney be movable, it will be felt between the fingers and can be made to slip up in a most characteristic way. The left kidney rarely falls to the same degree as the right. I have never observed it to fall below the umbilicus, while the right kidney frequently falls into the iliac fossa and even into the pelvis. It is remarkable that the left kidney feels much smaller than the right."

Health Resorts and Infectious Diseases. — The public of Great Britain, and doubtless the public of other countries, remarks *The Lancet*, still betray an almost criminal slackness as to the sanitary conditions, equipment, and administration of the "health resorts" to which each recurring summer the holiday-makers betake themselves. Business men, who, as members of their urban or rural district councils, have or ought to have sanitary matters constantly before them, give not a thought to the drainage, the water supply, or the isolation accommodation of the "health resorts" to which at no small expense they send their wives and children. Much less do they take the trouble to ascertain whether infectious diseases may be prevalent in the locality, or if perchance the previous occupants of the room or lodgings have suffered from such diseases. What a reform might be brought about in the sanitation of many of our so-called "health resorts," if, before selecting his annual camping-ground, the head of the family were to ask for certain information from the local medical officer of health!

Surgical Suggestions.

Amputation in Old People. — In old people we must be careful in the use of the Esmarch bandage not to crush the brittle arteries, and so cause thrombosis and sloughing of the flaps.—J. P. Dunn.

Treatment of Tetanus.—(1) Behring's tetanus antitoxin is an efficacious remedy of a specific character, and should be used at the earliest possible moment. (2) The earliest destruction of the infected area must not be omitted, as from it a permanent supply of toxin is provided. (3) The symptomatic treatment with sedatives, including narcotics, should go hand-in-hand with the serum treatment. (4) Other means of eliminating the tetanus poison should not be neglected. (5) Preventive serum treatment deserves further consideration. — Dr. Heddaeus, *Münch. med. Woch.*, March 29th.

Treatment of Harelip. — Dr. Mulford (*Boston Medical and Surgical Journal*, March 3d) gives a *résumé* of the important points, which include the following considerations: (1) Harelip babies are not necessarily feeble at birth, and by proper feeding can be kept up to the normal standard. (2) Keep the field clean with aseptic washes before the operation. (3) Operate in the sixth or the eighth week. (4) Do not slash with scissors, but cut and trim carefully with a knife. (5) Free the upper lip thoroughly from the jaw. (6) Anchor the nares with shotted wire. (7) Use no pins or heavy outside sutures. (8) Use *crêpe-lisse*, not surgeon's plaster. (9) Leave the heavy inside stitches for six weeks. (10) After operation, give special attention to the care of the bowels and to proper feeding, as on this very often hangs the whole success of the operation.

The Treatment of Appendicular Inflammation.—Dr. Joseph Eastman (*Medical and Surgical Monitor*, June) concludes that: (1) The unqualified dictum, "Operate as soon as the diagnosis of appendicitis is made," is unsound, unsafe, and often pernicious. (2) Appendicitis is a disease demanding surgical treatment at the hands of the expert in abdominal work, for the reasons: (*a*) In no abdominal operation is so thorough mastery of the principles and technique of asepsis necessary; (*b*) the operator with an experience of hundreds of abdominal sections can give the patient a better chance of life than one who only occasionally opens an abdomen. This need not deter any surgeon or physician from operating in an emergency. (3) After an attack of appendicitis the patient is carrying an open communication between the intestinal lumen and the peritoneal cavity, which, if temporarily closed, may open at any time by absorption of the exudate or adhesions which have temporarily closed the leaking sinus. (4) The cases cured (?) by medicine should, during convalescence from the cure (?) be submitted to a surgical cure in fact, not in fancy, for the reason that operation in the interval between attacks is less dangerous than are medical cures. (5) All cases in which an appendical abscess has been opened come under the same head as medical cures (?), and demand surgical cure in fact, not waiting for a second explosion of dynamite. (6) Who would think of living in a house with a burst, leaking sewer, sending out microbic infection and poison, depending upon the degree of filth, fæces, and fungous granulations or accumulations hermetically to seal up the opening? It would be contrary to all the best principles of correct science or good surgery and of sound sense. (7) "Surgery should be the handmaid of medicine, not supplanting her mistress nor yet usurping her rights, but rather assisting her to maintain them."

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 15, 1898.

INCOMPATIBILITY OF DISEASES AND PREDISPOSITION TO THEM.

THE hæmatological and clinical observations of the fevers from which our soldiers suffered during the late war have served to dispel the teachings in which most of the present generation of physicians were brought up, in reference to the incompatibility of malarial and typhoid fevers. There seemed to be no good and logical reason why a person suffering from typhoid fever should not be susceptible to infection with the malarial plasmodia, in the presence of conditions favorable for the production of the latter disease. The asthenia which so frequently goes with typhoid fever would seem to offer a *locus minoris resistentiæ* for all sorts of infection, including that of the plasmodium. Be this as it may, the theory of the coexistence of malaria and typhoid in the same patient was held by practically all teachers and clinicians to be fallacious, until the recent researches in connection with our sick soldiers demonstrated the contrary. It has now been proven beyond a shadow of doubt that mixed infection exists, and that malaria and typhoid may occur as distinct and separate diseases in the same patient. In tuberculosis we have a disease which shows a special predilection for the victims of certain ailments, and yet it seems carefully to shun those who are already suffering from other pathological conditions. Thus, tuberculosis is rarely found in subjects of chronic heart disease, particularly mitral stenosis and insufficiency. The chronic pulmonary congestion which results from the lesion appears to form an unfertile ground for the development of the tubercle bacilli. Moreover, if a tuberculous patient falls prey to a cardiac lesion, the phthisical symptoms, according to Ortner, are ameliorated by its presence. These remarks apply, of course, to lesions of the left heart; disease of the right heart, particularly pulmonary stenosis, favors the production of pulmonary tuberculosis, on account of the anæmia of the lung to which it gives rise. Turning to the respiratory apparatus, we find that tuberculosis rarely attacks the subjects of emphysema, bronchial asthma, or bronchiectasis. If it attacks an emphysematous patient, it runs a slow and chronic course. Neusser states that myxœdema, paresis, and chronic alcoholism contribute largely to the positive side; while Basedow's disease, tabes dorsalis, leukæmia, gout, and the uric-acid diathesis seem to protect against the disease. Generally speaking, carcinoma and tuberculosis do not go together. The exception to the rule is found in carcinoma of the œsophagus and of the cardiac end of the stomach, in which conditions tuberculosis is of common occurrence. This is explained by the fact that in the latter cases the circumstances are such as to favor cachexia, on account of the extreme difficulty in properly feeding and nourishing the patients. Bright's disease, in accordance with the teachings of the Vienna school, protects against tuberculosis. A primary tuberculosis, however, is not an infrequent source of parenchymatous and amyloid degeneration of the kidneys. Hysterical patients, for some unknown reason, appear to be immune so far as tuberculosis is concerned. If it develops at all in these subjects, the course is usually mild. Diabetes forms a favorable soil for the growth and development of the tubercle bacillus, and, according to Murchison, tuberculosis follows typhoid more frequently than any other fever. Finally, the catarrhal sequelæ of measles, whooping-cough, diphtheria, and scarlet fever often pave the way for the development of tuberculosis.

HAWAII FROM A HEALTH POINT OF VIEW.

HAWAII is now American territory, and with its annexation the government has taken upon its shoulders not only the responsibility of ruling, but also the task of looking after the health of its inhabitants and supervising the sanitary arrangements of the island. When the existing condition of affairs as regards matters hygienic and the state of public health generally in Hawaii is taken into consideration, it must be conceded that the labor will be Augean. For many years the Sandwich Islands have been hotbeds of disease, and, until drastic remedial measures have been put into force, are likely to remain so. In the MEDICAL RECORD of April, 1889, Dr. Prince A. Morrow, who probably is better acquainted with the subject than any one else, contributed some notes of observation on matters medical in the Sandwich Islands, which, although some few years have elapsed since they were written, will to all intents and purposes apply with equal truth to the present situation there. After referring to the physical and mental characteristics of the natives, Dr. Morrow says: "The demographic effects of introduced diseases in a virgin soil can nowhere better be studied, and they exhibit facts of the most remarkable interest. The natives have proven strangely susceptible to the diseases of civilized life, and trifling ailments, such as measles, whooping-cough, etc., acquire by their transplantation into this soil all the virulence of a fatal pestilence. Measles and whooping-cough, introduced in 1849, almost decimated the population; the mortality was excessive, almost every case terminating fatally. The ravages of smallpox, introduced in 1853, were none the less frightful. In the island of Oahu over fifteen thousand died, and the marshal of the islands informed me that he superintended the burial of ten thousand victims of this dis-

ease in Honolulu alone—more than one-half of its entire population. . . . The most important agency in the depopulation of the islands has been attributed to syphilis, which was introduced by Captain Cook and his men in 1778. The licentious habits and promiscuous intercourse of the inhabitants caused it to spread like wildfire through the islands."

Syphilis is still a terrible scourge in Hawaii, but of all the diseases prevalent there the most loathsome and deadly is leprosy. With regard to leprosy, Dr. Morrow says, in 1889: "Nowhere else in the world can be found a parallel to the extraordinary development and rapid spread of this disease, which in the short space of little more than one generation has attained such alarming proportions and proved such a terrible menace to the public health."

That matters have not changed much for the better in this respect, an article by Dr. Burnside Foster, in the *North American Review* of September last, would seem to demonstrate. Dr. Foster says: "Leprosy up to 1849 was unknown in the Sandwich Islands, at which date it was introduced by two Chinese sailors, and the disease has spread so rapidly that at the present time nearly ten per cent. of the Hawaiian natives are lepers."

Dr. Osler takes exception to these extreme views of the prevalence of the disease, but there seems to be no doubt that its ravages are very extensive. Although the lepra bacillus was discovered by Hansen so long ago as 1874, our knowledge with regard to its etiology has advanced but little; authorities are, however, unanimously agreed as to its contagiousness.

These being the facts of the case, what steps should be taken by the government of this country to prevent the spread and to endeavor to stamp out the disease, root and branch? Dr. Foster, in the article referred to above, emphasizes the necessity of creating a department of public health, with a minister in the President's cabinet, and also suggests the appointment of a leprosy commission to investigate the disease on the spot, and to make, so far as is possible, an accurate census of the lepers of Hawaii, and to see that all infected persons are completely segregated. There is yet another important point to be considered, to which Dr. Foster draws attention—that the government must educate the people—the soldiers, civil servants, and those who go to Hawaii for commercial purposes and who are likely to be brought into contact with lepers—in regard to the dangers of infection and the precautions necessary to be taken. The end in view should be the total extinction of leprosy. This result can be attained only by the complete segregation of those afflicted, which is impossible until our knowledge of the etiology of the disease is more precise and accurate than at present. Therefore, the first move on the part of the United States should be the immediate appointment of a properly organized and equipped bacteriological commission. To devise means to extinguish the foul disease of leprosy would redound as much to the glory and credit of America as did the discovery of vaccination to England or the discovery of the principle of serum immunization to France.

SOME REFLECTIONS ON THE ENGLISH VACCINATION BILL.

The reasons for passing the new vaccination act in England are scarcely understood in this country. Doubtless the government has been weak minded in thus deferring to the wishes of a minority, to the imminent danger and risk of the great body of the people, and probably the wiser and safer policy would have been, as the *Times* suggested, to make more stringent compulsory vaccination laws, and to see that they were properly carried into effect. Here in America, however, we have no conception of the organized agitation which has for so many years been carried on against vaccination in England. It is, without doubt, true enough that the opposition was an inconsiderable minority, but it was a minority continually in evidence, noisy, vehement, and irrepressible. The physicians in England, too, were greatly to blame for the state of affairs, in that they took no pains to controvert the arguments of the antivaccinationist faddists, and made no attempt to educate the more ignorant members of the community as to the benefits conferred by vaccination, in consequence of which every false and misleading statement was firmly believed in. Latterly things have arrived at such a pass, that some steps had to be taken to offset the disgraceful condition of chaos into which the carrying out of the vaccination act had fallen; and, although the mode of procedure decided upon to reach this result is generally believed to be a mistaken one, yet it will at least have the effect of knocking from their hands the most powerful weapon used by antivaccinationists against a compulsory measure. There will be no opportunity now to pose as martyrs. The situation under the new act is, according to a newspaper writer, in brief as follows: Within four months of the birth of a child (or of the passing of the act in the case of children previously born) the parent will be visited at his home by the vaccination officer; and if in the absence of a certificate of conscientious objection the parent refuses to allow the child to be vaccinated, he will be liable to prosecution twice only till the child is fourteen years old. The alleged dangers of the operation are reduced to a minimum, so far as modern science has enabled human foresight to provide against them. It will therefore be observed that everything possible, with the exception of a total repeal of the vaccination laws, has been done to study the wishes and defer to the susceptibilities of the opponents of vaccination; but those in England who know assert that all this will be of little avail. *Public Health*, commenting on the matter, says: "That the organized opposition against vaccination will be propitiated by the large concession thus made to it, or by the important improvements which the act introduces in the shape of glycerinated calf lymph and domiciliary vaccination, it seems hopeless to expect. The antivaccination league has, since the bill was passed, given ample proof that its hostility to vaccination is in no degree mitigated. Nothing less than the entire disestablishment of the 'Jennerian rite' will satisfy it, and we may therefore reckon with certainty on a

continuance of the methods of misrepresentation and casuistic perversion, which it has so persistently practised for years past." This statement, if true, and there seems no cause to doubt its truth, gives the promise of a pleasant outlook for those peaceful, law-abiding inhabitants of England who believe in vaccination and who form the large majority of the population. It may appear a cruel prediction, but probably the only solution of the difficulty would appear to be the occurrence of a severe and widespread epidemic of smallpox. Such an event would at any rate rouse from their lethargy the great mass of the people, who would doubtless then insist that the health of the community at large should not be sacrificed to the fads of an irreconcilable minority. The action taken by Lord Lister in the matter has given rise to some surprise, both here and in England. There is no doubt that if he had not given the bill his qualified support and spoken in its favor it would have been again rejected by the house of lords. However, it must not be argued from this fact that Lord Lister has in any way lost his faith in the efficacy of vaccination. He believes in it as strongly as ever he did, but he was on the horns of a dilemma. He had to choose between the withdrawal of the bill, as recommended at the meeting of the British Medical Association, and an acceptance of it in its present form, as a makeshift tempered by the promise of early legislation to supplement its defects. In short, the bill is a sop to the antivaccinationists and an experiment. We are of opinion that both Lord Lister and the government have erred greatly in trying so risky an experiment, and in this country we shall be content to travel in the same path as sensible little Scotland and hold fast by compulsory vaccination.

THE STUDY OF TROPICAL DISEASES.

The *British Medical Journal* of September 24th may rightly be termed a tropical number, as, besides a full report of the proceedings of the section on tropical diseases at the meeting of the British Medical Association and other contributions bearing on the same subject, all the leading articles and the greater portion of the editorial matter are devoted to the consideration of the diseases prevalent in hot climates. Thus the issue will be found most useful to those interested in the matter, and a valuable addition to its constantly increasing literature. In the first instance it is pointed out that, notwithstanding her unique opportunities for studying the diseases incidental to the tropics among her many possessions in those regions, England has up to a comparatively recent date taken but a languid interest in the subject. Germans, Italians, and Frenchmen have all taken the lead, while, to quote the *British Medical Journal*, "the rising American school of pathologists, particularly those of the Johns Hopkins University, also stepped in and did much to impart new life to what, so far as the British branch of the Anglo-Saxon race was concerned, was a languishing subject." All this has, however, within the last few years, undergone a complete change, and the anxiety now displayed by British scientific men —in a manner of speaking—to make up for lost time is highly laudable and augurs well for the future.

To Dr. Patrick Manson is greatly due the impetus given to this branch of study, as well as to Maj. Ronald Ross for his valuable investigations in working out and placing on a practical basis Dr. Manson's theories. Referring to the activity now being exerted in the field of tropical research generally, and more particularly to the investigations of Ross, the *British Medical Journal* remarks: "As an example may be cited the case of Ross' remarkable discoveries. Results of the utmost value to humanity may very well acrue from Ross' demonstrations that the mosquito is an element in the propagation of malaria. This fact distinctly points to the possibility of a practicable prophylaxis to this worst scourge of mankind—a prophylaxis which, if effected, will do more to open up and civilize Africa and other dark places of the earth than even the sirdar's brilliant victories."

The series of articles in our able contemporary concludes with one on the much-disputed question as to whether the white man can ever become properly acclimated in tropical lands, and some articles recently contributed to *The Times* by Mr. Benjamin Kidd are taken as the text for discussion. Mr. Kidd gave it as his decided opinion that it is absolutely impossible under any conditions for the white man to thrive physically in the torrid zone. This dogmatic assertion is strongly combated by the writer in the *British Medical Journal*, who not only brings forward against this contention the opinions of such authorities as Dr. Sambon, but shows that in those places—as Jamaica, for instance—which at one time were veritable hotbeds of disease efficient sanitary measures have had the effect of converting them into quite healthy localities. This appears to us to be sound and fairly conclusive reasoning, and we may with confidence look forward to that time when the deadly diseases of the tropics will have been grappled with and conquered by the aid of modern science.

Ecclesiastical Disapproval of Clerical Quacks.—The priestly quacks at Woerishofen, who have succeeded to the water-cure business of the late Father Kneipp, have recently suffered a rebuke from the bishop of Augsburg, in whose diocese they are. "Certain regrettable statements," the bishop writes, "which have recently been put forth by men not justified through sufficient learning to enunciate them, but moved thereto by hope of gain, constrain us to warn in the strongest terms our beloved sons of the clergy and laity in the diocese of Augsburg to observe in all particulars the decrees of the Roman Church promulgated against the illegal practice of medicine by those whose lives are consecrated to the service of God in His sanctuary." The clergy are also exhorted so to comport themselves as not in any way to interfere with the practice of individual physicians, and also to keep on terms of friendship and mutual co-operation with all the lawful members of the medical profession in their parishes.

News of the Week.

The Yellow Fever in the South is spreading rapidly through Mississippi, and bids fair soon to have the entire State within its grasp unless a killing frost puts a stop to it. Up to October 9th the total record of yellow fever for the summer is as follows: Louisiana, 704 cases and 33 deaths; Mississippi, 435 cases and 35 deaths. One case is reported from Arkansas, and 1 case and 1 death from Kentucky, among the Mississippi refugees. Total cases, 1,141; deaths to date, 69. The disease has been reported from thirty-five different places. The Mississippi State board of health despaired long ago of confining the infection, and is now devoting itself chiefly to the work of relief and of securing nurses for the places that are stricken. An appeal has been made to the federal government, but under existing laws the Marine Hospital service can only establish detention camps and maintain a corps of inspectors and physicians, but cannot furnish nurses or supplies. The State officials have been seized by the general panic, and, with the valiant governor at their head, have deserted their posts at Jackson and are in hiding in some out-of-the-way places. As soon as the yellow fever threatened to become epidemic, Governor McLaurin took his private secretary and transferred the executive department of the State government (very appropriately) to the insane asylum, two miles from Jackson. But this was too near his post of duty (and the yellow fever), so he gathered up his family and tried to get to his home at Brandon; but the people there wanted no possibly fever-infected governor, so they told him to march on. Since then he has not been heard of, and may still be running. Most of the other State officers have followed their official head, and no one remains in the capital, even to receive taxes. Nearly all of the whites who can, have fled from the infected districts, and the poor negroes are inclosed within a strict cordon, without any of the necessaries of life, in true reconcentrado style that would put Weyler to the blush. The wretched sufferers crowd as near to the line as possible, and beg for food for themselves and their families. The panic-stricken whites will not let them out, and have made no provision for their sustenance. The mortality from the disease continues low, but will doubtless begin to rise if starvation is added to disease.

The North Hudson County (N. J.) Medical Society was organized September 29, 1898, when the following officers were elected: *President*, Dr. E. J. Kuehne, of Jersey City; *Vice-President*, Dr. E. C. Armstrong, of Union; *Secretary and Treasurer*, Dr. A. J. Walscheid, of Union. The society began with twenty members, and four new members were admitted at a meeting held on October 6th.

New York State Medical Association.—The committee of arrangements has secured a reduction in railroad fare from the Trunk Line Association, of one and one-third fares for the round trip, to members of the New York State Medical Association and their families visiting New York at the time of the meeting —October 18th, 19th, and 20th—provided that one hundred persons who pay full first-class fare of seventy-five cents or upward, coming to the meeting, avail themselves of this privilege. To make this reduction effective, certificates must be obtained from the ticket agent at the starting-point or nearest station issuing through tickets to the place of meeting. This certificate, to be valid for the reduction on the return fare, must be indorsed by the chairman of the committee of arrangements, and *viséd* by a special agent of the Trunk Line Association, who will be present at the place of meeting for that purpose on October 19th and 20th. The committee has also completed arrangements for a banquet at the Manhattan Hotel, Madison Avenue and Forty-second Street, which will take place on the evening of October 19th. Already over one hundred have signified their intention of being present. Dr. F. H. Wiggin is chairman of the committee of arrangements.

Diphtheria Quarantine.—The Boston board of health has made a new rule, requiring two consecutive negative cultures from the throat before granting the release from quarantine of diphtheria patients. The general rule with boards of health throughout the country has been to refuse release from isolation until one negative culture at least has been obtained. But investigations carried on in the Boston health department show that in very nearly one-third of such patients, released on the evidence of a single negative culture, the Klebs-Loeffler bacillus is still present.

Drumming for the Quacks at Hot Springs.—A special agent of the department of the interior has been making an investigation of the condition of affairs at the Hot Springs reservation in Arkansas, and reports the existence of a number of abuses. The report says: "By far the most serious question in connection with Hot Springs affairs, and the one which menaces the life and health of persons who go there seeking treatment, is the practice of drumming. There are drummers for three different businesses at Hot Springs, viz., drummers for bathhouses, drummers for hotels and boarding-houses, and drummers for the doctors. The most harmful thing, however, to Hot Springs, for the reason that it is the most dangerous thing for persons who go there for treatment, is the present system of doctor drumming. There are a great many doctors in Hot Springs who are notorious in the matter of having drummers for their business. The custom about this is that strangers are met on the trains and in towns more than one hundred miles away from Hot Springs by drummers for these doctors. The drummers make the point, before taking the victim to the doctor, to ascertain relatively his financial standing, then to advise the doctor as to this matter, and the man is duly fleeced." It is said that two United States senators were among the victims last winter. The interior department is seeking for some way to put a stop to these abuses, but finds itself hampered by the fact that the reservation is under the judicial control of the State of Arkansas, and it is said that

the State laws have many loopholes through which these irregular practitioners can escape. In order to stop the drumming, the department proposes the adoption of a regulation providing that no bathhouse receiving water from the Hot Springs reservation shall permit any person to bathe therein who has not a certificate from a reputable physician, who does not resort to drumming. The superintendent of the reservation or a board of surgeons, to be appointed by the secretary of the interior, will be required to certify to the professional standing of physicians prescribing baths at Hot Springs, and no one who is known to drum for custom will get a certificate which will entitle his patients to bathe at the bathhouses.

A Bequest to the University of Vermont.—The will of the late Dr. Thomas Seton Robertson, of this city, after providing for legacies of mementos to various friends of the deceased, bequeaths all the residuary estate, estimated at about $5,000, to the medical department of the University of Vermont (Burlington, Vt.), for a fund to be devoted annually to the purchase of microscopes as prizes for students.

An Offended Osteopath.—A man, called William Smith, M.D., D.O., has brought suit against the *Medical Age* for $25,000 damages because of an alleged libel, the editor of the journal having spoken disrespectfully of another man, named Still, who is accredited with being the founder of "osteopathy," whatever that may mean.

Medical Inspection of Schools in St. Louis.—The members of the Medical Society of City Hospital Alumni of St. Louis have offered their services gratuitously to the board of education for the purpose of conducting a daily medical inspection of the pupils in certain schools, in order, they say, that a practical local test may be made of a service that has been found so valuable in a sanitary sense in other cities. It is proposed to select ten schools, which will fairly represent the entire school population, and have them visited daily, during October, November, and December, by physicians whose duty it will be to advise the several principals in the cases of pupils found ailing, and suggest the most judicious course to be pursued—the object of the service being the earliest possible detection of such diseases as diphtheria, scarlet fever, croup, etc., and the prevention of their further spread. This offer has been accepted by the St. Louis board of education, and the preliminary details are now being worked out by the committee of the Medical Society of the City Hospital Alumni.

Behring's Degradation.—We are all the more surprised that Professor Behring should have applied for such preferential rights, more especially as he never was instrumental in making the theory—which he, in conjunction with Professor Kitasato, had put forward—practical for the treatment of diphtheria in mankind. This was reserved for Dr. Aronson, who first succeeded in making from the horse a serum of sufficient strength so as to make it practical for the checking of the disease itself. So far as Behring and Kitasato had gone in making serum from the goat and calf and other minor animals, they never had the courage to expect or to pretend that the serum they produced, and which was of very inferior strength, would be a remedy for diphtheria in mankind such as Aronson showed he could supply. They had contented themselves by having found some serum likely to be used for inoculation purposes, similar to the lymph of small-pox. Dr. Aronson had a right to a patent for developing a minor theory into a grand remedial agent never before dreamt of, but he never enforced his claim, for obvious reasons.—*The Therapist.*

A Miscarriage of Justice.—A physician in Peoria recently brought suit to recover fees, before the magistrate's court. A jury was summoned, and, after hearing the testimony, not only disallowed the account, but, upon the mother's plea that her daughter was not benefited, actually assessed against the attending physician the sum of some $30, to reimburse the mother for services as nurse in the case.—*Peoria Medical Journal.*

The Medical and Commissary Departments in the Soudan Campaign.—Lord Kitchener, in his report of the Omdurman expedition, published last week in London, warmly commends the commissary, medical, and transport departments. The sirdar speaks with special emphasis of the "excellent rations which were always provided and kept the men strong, healthy, and fit to endure all the hardships of an arduous campaign, enabling them at a critical moment to support excepitonal fatigue, continuous marching, and fighting for fourteen hours during the height of a Soudan summer."

Apparent Increase of Insanity in Ontario.—In a recent report of the Ontario asylums inspector, it is stated that each month of the present year has witnessed an increase over its predecessor in the number of inmates in the lunatic asylums. The number of inmates in August was 5,032, while that of July was 5,011. There are only 35 vacancies in all the asylums in the province, and 90 former inmates are out on probation, while 48 are confined in jails. The increase is thought to be due to the fact that mentally affected persons are more closely looked after now than formerly.

Notification of Venereal Disease in Prussia.—A circular was recently sent by the police authorities to all the physicians in Berlin, directing their attention to the Prussian regulations for the compulsory notification of cases of venereal disease. Notification is not obligatory for all cases of syphilis or gonorrhœa indiscriminately, but for those only in which, in the opinion of the doctor, secrecy might be followed by harmful results to the patient or to the community. Civil physicians treating syphilis in soldiers must report all such cases to the commander of the regiment or the chief surgeon. Surgeons who have cases of venereal disease in their practice are called upon to search out the person from whom the infection has been conveyed, and, wherever necessary, to report such person to the police.

Reviews and Notices.

RECHERCHES CLINIQUES ET THÉRAPEUTIQUES SUR L'ÉPILEPSIE, L'HYSTÉRIE ET L'IDIOTIE. Compte rendu du service des enfants idiots, épileptiques et arriérés de Bicêtre pendant l'anée 1897. Par BOURNEVILLE, avec la collaboration de MM. DARDEL, JACOMET, METTETAL, J. NOIR, PHILIPPE, RELLAY, SCHWARTZ, TISSIER et WUILLAMIER. Paris: Librairie du *Progrès Médical* et Felix Alcan. 1898.

THE eighteenth volume of Bourneville's "Researches" is quite as interesting as any of its predecessors. It gives abundant evidence of the immense strides made by pedagogy in the treatment of defective and idiotic children. The contributions to the morbid anatomy of idiocy and of symptomatic epilepsy deserve special mention. The work being done by Bourneville and his collaborators is deserving of the highest praise.

CLINICAL MANUAL OF MENTAL DISEASES. By A. CAMPBELL CLARK, M.D. New York: Wm. Wood & Co. 1898.

NO one interested in mental diseases can read this book without a keen sense of disappointment. It merits the unenviable distinction of being less up to date than almost any work of its kind. It is inaccurate in statement, inelegant and unpolished in expression, and decidedly unscientific. All that can truthfully be said in its favor is that it contains some interesting clinical histories and a few expressive photographs to illustrate the physiognomy of the insane.

LEHRBUCH DER NERVENKRANKHEITEN. Von PROFESSOR DR. OPPENHEIM. Second Enlarged Edition. Berlin: S. Karger. 1898.

OPPENHEIM'S text-book of nervous diseases has well merited a second edition. It is one of the most readable and helpful books on neurology in the German language. The author has for many years been known as an indefatigable worker in his chosen field, who has won the confidence and approbation of his fellow neurologists, both at home and abroad. The first edition of his book was accorded deserved praise in these columns, and we are glad to say that the book in its present form will be found both by the student and the practitioner to be a trustworthy, scientific, up-to-date exposition of the diseases of the nervous system. Standing as it does midway between the many compendiums on diseases of the nervous system and the exhaustive treatises, it has, in a way, a very important field, which it possesses admirably. The letter press and illustrations have been executed in a most commendable manner.

OVARIOTOMY AND ABDOMINAL SURGERY. By HARRISON CRIPPS, F.R.C.S., etc. Philadelphia: P. Blakiston's Son & Co. 1898.

THE combination of gynæcology with general abdominal surgery in a descriptive work is a good one. It calls attention to and emphasizes the fact that there is nothing in gynæcological surgery that makes it radically different from general abdominal work, and that in consequence the general surgeon ought to be prepared to cope with the surgery of the female pelvic organs. The author of this work has given us a comprehensive review, and one sufficiently detailed for all ordinary purposes. The colored plates are above the average in technical execution, but perhaps do not fulfil their purpose any better than less elaborate ones. The descriptions of the operations are, as a rule, good, but offer nothing novel. There is a good deal of the author's personal equation in them. The latter portion of the book is devoted to a long series of clinical histories of cases operated upon by the author, many of them of great interest and statistical value.

DISEASES OF THE NERVOUS SYSTEM. A Handbook for Students and Practitioners. By CHARLES E. BEEVOR, M.D. Philadelphia: P. Blakiston's Son & Co. 1898.

THE writer states in his preface that the objects of this handbook are to enable students and practitioners to know how to examine patients suffering from diseases of the nervous system, and to assist them in marshalling their facts in a definite order, and also to serve as an introduction to the study of the larger standard works on neurology. The reviewer desires to say at the outset that the writer does not convince him the objects have been attained. Only thirty-five pages are devoted to history taking and modes of examination. The author says nothing new and oftentimes puts that which he has to say very badly. It would not have been difficult for him, it would seem, to hit upon a more elegant heading for Chapter III. than "Method of Taking a Case." There are those who "take cases" by method, and those who do not.

The author's style is obscure, his diction oftentimes unpleasantly involved, and his phraseology is not devoid of such British barbarisms as "acuity," "it is as," "purposeless vomiting," etc. We do not admit that it is necessary to impress on the student that "in examining the mental condition of a patient, we should ascertain if he is comatose;" no more do we believe that the average student can make anything out of this: "The extent, distribution, and grouping of the paralyzed muscles will correspond to the anatomical motor supply of a peripheral nerve when the ulnar or median nerve is affected, and the loss of sensation will correspond to its anatomical sensory distribution." Nor can he make sense of "The general and functional diseases are arrived at after the organic diseases have been excluded," unless it dawns upon him that the author is thinking of diagnosis. It is scarcely worth the time to point out in detail the errors of omission and commission of this manual. If the book had virtues that counterbalanced its shortcomings, we would not refer to them at all, but it has not. A volume on nervous diseases in 1898 which says nothing of infection and epidemic occurrence in discussing anterior poliomyelitis; which asserts that in Landry's paralysis "as a rule nothing has been found post mortem," and that loss of sight which may become absolute is rather a common early symptom of locomotor ataxia; and does not mention Fränkel's method of re-educating the ataxic extremities in the treatment of tabes, does not appeal to us, nor can we recommend it to others, much as it would delight us to do so. With such compendiums of diseases of the nervous system to compete with as that of Dana the new comer must have genuine merit, if it expects to be admitted in the same class. That the one in question cannot be, it scarcely need be said.

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Abstract of the Proceedings of the Twenty-Sixth Annual Meeting, Held at Ottawa, Canada, September 27, 28, 29, and 30, 1898.

THE association met in the railway-committee room of the house of commons, under the presidency of Dr. Charles A. Lindsley, of New Haven, Conn.

At the opening session twenty-six applications for membership were read and acted upon favorably.

Resolutions were presented by Mr. Henry Lomb, setting forth the desirability of sustaining all existing voluntary sanitary organizations and outlining a plan for the multiplication and extension of them. He said that the most promising direction in which energetic efforts could at present be exerted would be to devise and establish on a permanent basis a system for the instruction and training of persons who were already pursuing, or who might desire to engage in, the business of sanitary inspection. The association adopted this resolution:

"*Resolved*, That while the association recognizes the value of the local auxiliary sanitary societies in many of the States, yet effectual enforcement of the laws and ordinances designed to prevent the spread of diseases can best be assisted by supplying for employment by executive health officers men who have been taught the art of hygiene."

DR. C. L. WILBUR, of Lansing, Mich., offered the following resolutions, which were referred to the executive committee:

"*Resolved*, That the American Public Health Association earnestly recommends that a plan be incor-

porated in the act to provide for the taking of the next United States census, whereby reliable representative vital statistics may be secured for the non-registration States.

"*Resolved*, That the Association recommends that the Bertillon classification of causes of death be adopted by all the registrars of vital statistics in the United States, Canada, and Mexico, as soon as the change from the systems now in use can be conveniently made.

"*Resolved*, That the committee on nomenclature of diseases and forms of statistics be authorized to have printed and circulated among the registrars of the three countries a circular containing these resolutions, the report of the committee on which it is based, the three alternative forms of the Bertillon classification with explanatory notes on inclusion of terms and practical rules for compilation, and a list of the registration offices adopting the same.

"*Resolved*, That a proposal be made for an international alliance between the registrars of the three countries included in this association and the registrars of France and other countries now using, or which shall hereafter adopt, the Bertillon system, and that definite plans for such an alliance shall be submitted for action to the next annual meeting of this association."

The executive committee subsequently recommended the adoption of the above resolutions, and they were unanimously concurred in by the association.

An Outbreak of Typhoid Fever Due to an Infected Water Supply.—Dr. John L. Leal, of Paterson, N. J., read this paper. The author dealt with the pollution of the water supplied to the residents of that city. The outbreak established the fact that the germs originating in a single case of typhoid fever might infect even a large body of water, so as to reproduce itself among those dependent upon the same body of water for their public supply, even though the supply might be taken at a point some distance from the focus of infection. The cases of typhoid in the present instance had developed as followed: During the last half of September there were 26 cases; October, 41 cases; November, 108 cases; December, 58 cases. The disease was evenly distributed throughout the city, except in one district containing about two thousand people, and among all classes of the inhabitants. No possible common means of infection could be found except the public water supply, upon which all of those infected, with the possible exception of two or three, were dependent for at least a portion of the twenty-four hours. The only section of the city which did not contain a single case was not furnished with a public water supply. The water was taken from the Passaic River. No evidence of harmful pollution above the falls was shown. Chemical evidence of harmful pollution below the falls was found. After stating the time during which infection existed in the stream, the speaker related the case of a patient who had returned from a summer resort suffering from typhoid, who practically recovered but later was taken with a relapse, which lasted about a month before convalescence began. The river had been more or less continuously infected by cesspools from September 1st until November 24th, when the discharge pipe was discovered and further infection from that source prevented.

The Cause and Prevention of Infectious Diseases.—Dr. Peter H. Bryce, of Toronto, read an exhaustive report as chairman of the committee on this topic. He stated that infectious diseases must be divided as regarded their mode of causation and their growth and development. With reference to the methods for suppressing outbreaks of diphtheria in a community, he said that further experience in Ontario during the past year had shown that the following seemed the most effective and prompt means of stamping out an outbreak: In a number of municipalities where the disease appeared, as it always did, principally among school children, the practice was introduced of a morning visitation by the sanitary inspector to all the public schools to obtain a list of the day's absentees. The homes of these were promptly visited, and where any evidence of malaise and sore throat was present the parents were at once required to send for a family physician and have a swab taken and forwarded to the medical officer by the afternoon. This was sent at once by mail to the laboratory, and the patient isolated until an answer by telegraph of the result of the examination was received. When the case proved to be diphtheria, the patient was isolated until further examination proved the freedom of the throat from bacilli. The children of the household were kept from school and the public, and the home subsequently disinfected with formaldehyde when the child had not been removed to the hospital. The essayist then briefly referred to the progress made in medical knowledge, both with regard to the inoculation and dissemination and prevention of tuberculosis. The experiments of Pflügge regarding the dissemination of dust and germs of disease by air movements in houses went to show that in those cases in which inhalation infection had been successful sprayed moist sputum had always been used. The author concluded that in diphtheria, scarlet fever, consumption, influenza, etc., there was more danger from the infecting agent thrown into the air by the act of coughing than from dust derived from the same material. He referred to the extreme danger attaching to inmates of the same houses where cases of consumption in advanced stages were resident.

What Constitutes an Epidemic?—Dr. Benjamin Lee, of Philadelphia, read a paper on this subject, in which he claimed that if a dozen cases occurred in rapid succession from one case, then an epidemic existed. He referred to the indisposition of communities to admit the existence of epidemics, owing to the injury to commerce which was likely to result. His contention was that the actual number of cases of a contagious disease in proportion to the population as a criterion for the declaration of an epidemic had nothing to do with the matter. He thought that rapidity of spread should be solely considered. "The board of health which, having knowledge of such conditions, purposely conceals it, or, still worse, denies it, is guilty of a crime of hideous proportions, none the less so because it is acting in obedience to the behests of the business portion of the community or from a mistaken sense of local patriotism."

The Urgent Need of Sanitary Education in the Public Schools.—Mrs. Ellen H. Richards, of Boston, contributed a paper on this subject. She said the average American citizen had not accepted the teaching of sanitary science as a part of his creed. The remedy for this ignorance was to be found in securing the correct teaching of the elements of public hygiene in the public schools of the country. The diseases among American soldiers in the late war were caused, in her opinion, by culpable ignorance among the officers. Clean schoolhouses, clean streets, and special education cost money, which municipal officials claimed it was impossible to get; but the fact should be brought home to the community that the cost of needless sickness and death among our soldiers would have paid for the cleaning of every schoolhouse in the land, and the amount of the pension money would be more than sufficient to keep them clean. She advocated the appointment of a committee to prepare a primer which should contain the essential principles of preventive medicine, and which could be

as universally taught as was first aid to the injured. Good cooking was also a factor in preventing disease.

At the evening session of the first day addresses of welcome were delivered by the Hon. Sydney Fisher, M.P., Sir James Grant, the mayor of Ottawa, and Alderman W. G. Black. The response to these various addresses was made by the president of the association, Dr. Lindsley.

Annual Address.—Dr. Benjamin Lee then took the chair, and President Lindsley delivered his annual address. He said that the primary and ultimate purpose of the association was the protection and preservation of the public health. Sanitary science was based on the correct interpretation of facts. The verification of a single fact often involved a long investigation. For example, there was such significance in the fact that civilized man lived longer than the savage that this had arrested the attention of close observers, and prompted inquiry into the special factors in civilization which had caused this result. Civilization was a power exerting an influence upon human life in many directions. The conditions of modern civilization contributed powerfully toward lengthening life, if the average of a large community was the basis of measurement. Social practices of so-called civilization might prematurely cut the thread of life and so diminish its average duration. Dr. Lindsley reminded his hearers of the progress made in medical science during the past few years. Not many had had personal observation of the plague, of leprosy, of scurvy, of typhus fever, or of yellow fever. Civilization was an evolution. It was progressive, developing new features with every advance. Health organizations were themselves a development of civilization. He said that England led all other countries in public sanitation. In Canada, Mexico, and in many States in America they were illustrating, as yet imperfectly, an ideal system. He dwelt at length on the system of looking after the health of the public, which, in his opinion, was an excellent one, and said the public intelligence should appreciate the value of it. He advocated a public chemical and bacteriological laboratory, and said a central board of health was not fully equipped without one.

Etiology of Yellow Fever.—Dr. Henry B. Horlbeck, of Charleston, S. C., chairman, presented the report of the committee on the etiology of yellow fever. Reference was made to the labors and experiments and discoveries of Sanarelli. A number of enlightened colleagues of this distinguished laborer had been engaged in verifying and extending his researches as to the cause of this disease. Sanarelli claimed that he had found the bacillus icteroides in fifty-eight per cent. of the cases examined, and believed that the reason of his non-success in always finding it was due to incidental causes. The author gave a description of the bacillus of yellow fever, and then referred to the work of other investigators. Drs. P. E. and John I. Achinard, of New Orleans, had studied the subject in relation to diagnosis by the bacillus icteroides by the Widal method. In fifty cases of yellow fever agglutination with cessation of motion was obtained in over seventy per cent., the reaction being as characteristic as in typhoid fever. The work of these gentlemen demonstrated: First, the practical value of serum diagnosis. Second, it might be utilized as early as the second day. Third, that a dilution of 1 in 40 with the time limit of one hour was to be preferred for accuracy in diagnosis. Fourth, the dried-blood method of Dr. Johnston was perfectly satisfactory. Fifth, the serum diagnosis of yellow fever should be instituted in all countries wherein the disease might exist endemically or which might be occasionally visited by epidemics. Sixth, it was especially valuable at the beginning of epidemics in the diagnosis of early and doubtful cases. The universal consensus of opinion in the enlightened scientific world was that yellow fever was due to a specific organism, and that while the bacillus icteroides might not be the inevitable cause of the disease, it was still of sufficient importance to warrant its closer study.

As a supplement to the report, Dr. Doty, of New York, stated that his researches indicated that the antitoxin serum possessed rather weak preventive power. Experiments made to determine its curative power had yielded negative results. His investigations on the subject of vaccine or a prophylactic fluid would indicate that the bacteria isolated from cases of yellow fever had preventive powers when prepared and inoculated according to the methods of Koch and Haffkine.

Dr. Eduardo Licéaga, of Mexico, read a sixth report on the etiology of yellow fever. This disease, he said, was defined as a febrile affection of a contagious character, which prevailed endemically in certain parts of the republic of Mexico, and sometimes assumed an epidemic form. The only centre of the disease that existed on the coast of the Mexican republic was found in the canton of Vera Cruz. In no other part of the Gulf coast did yellow fever ever make its appearance spontaneously. The disease had been transmitted through the bagging in which were carried corn, sugar, and coffee. It had also been transported in the clothing of persons who had been attacked, and also in skins exported from the places in which the endemic existed. Another material which served to propagate yellow fever was the ballast shipped by vessels in Vera Cruz after having landed cargoes. The propagation of the disease through the medium of water was not well established, although it was a probable cause of its spread. The general conditions that favored the transmission of yellow fever were humidity, heat, want of light and of ventilation. Sanarelli believed that mould afforded protection to the yellow-fever germ, and that once it found a lodging in the mould it was preserved in houses, ships, and other objects that could serve as a medium of transmission. The same author believed that mosquitoes could serve the same purpose.

Prevention of Infant Mortality.—The report of the committee on the cause and prevention of infant mortality was read by the chairman, Dr. Ernest Wende, of Buffalo, N. Y. He said that the utmost care must be exercised so as not to confuse diphtheria with some trivial disease, it being perfectly obvious from its dangerous character that it was essential to make a diagnosis as early as possible. Reports from the smaller communities bore ostensible evidence of absence of vigilance for the wholesomeness of water and the milk supply, this being a most important feature of public sanitation, requiring a fearless surveillance and systematic investigation in relation to all infectious diseases. He said that several scarlet fever and diphtheria epidemics had been averted in Buffalo by promptly tracing the source of infection to a particular milk route. Most satisfaction was found in the general condemnation of the long-tube, death-dealing nursing-bottle. Buffalo, through its city health department, had interdicted the use of the long rubber tube, as a consequence of which a suit was now pending in the courts to test the validity of such action, the suit being prompted by commercial interests. In preparing for this litigation, to be able to demonstrate the danger of such nursing-bottles and the justification for suppressing them, the department of health had resorted to a series of microscopical, bacteriological, and chemical investigations, which revealed innumerable bacteria of varied morphology.

Bovine Tuberculosis.—Dr. Irving A. Watson, of Concord, N. H., read a paper entitled "Some Observations from Practical Experience with Bovine Tuber-

culosis in New Hampshire." He gave a brief history of the official recognition of bovine tuberculosis in his State, and presented the following deductions: (1) It was impossible to eradicate bovine tuberculosis, but it might, without inflicting too great a burden upon the State, be reduced to a degree that would subserve the interests of the stock raisers and likewise protect the public health. (2) But a very small percentage of animals infected with tuberculosis in any way endangered the public health, and the indiscriminate slaughter of the cattle reacting to the tuberculin test was wholly unnecessary, inasmuch as many of them either recovered or the disease was permanently arrested. (3) A proper sanitary condition of stables and stable inclosures would do more toward preventing the spread of bovine tuberculosis than any other measure that could be adopted. (4) The danger of infection from bovine tuberculosis might be reduced to very small proportions, if not wholly eradicated, by sanitary measures, inspections, and physical examinations by the State in co-operation with local authorities. (5) Such inspections, once inaugurated, could be maintained without an expense that would be burdensome to the State.

Compulsory Vaccination. — Dr.. M. Septien, of Queretaro, Mexico, read this paper. He stated that compulsory vaccination was not carried out from the year 1878 until 1884, and in 1885 such a strong epidemic broke out that in nine months in Montreal thousands were attacked by small-pox, causing the death of thirty-five hundred persons. He cited this as one of the most noted examples of the rapid spread of small-pox. A Pullman-car conductor arriving from Chicago, where he had contracted the disease, was the vehicle of infection. Other examples were given, showing the disastrous effects of the indolence or the preoccupation of the masses and the negligence of the authorities.

Report of the Committee on Demography and Statistics in their Sanitary Relations.—The first part of this report, which was read by the chairman, Dr. Cressy L. Wilbur, of Michigan, recommended the adoption of the Bertillon system of classification of causes of death by the association, on the ground that it would render the mortality statistics of different States, provinces, and countries, fully comparable by sanitarians and others, and thus lead to great improvements in sanitation. Reliable and thoroughly comparable mortality statistics were absolutely essential for the use of sanitarians, and deductions based upon them were recognized as being of the greatest practical importance in public-health work. The association had now the opportunity to unify the statistics of a continent, besides bringing the work of mortality registration in North America into the closest relations with European statistics. At present the classifications used in the various States were in a chaotic condition, nearly every one being different. This was true, even when the general system was apparently the same, so that data could be compared in the different registration reports only with the greatest uncertainty. The progress of the classification recommended had been so rapid in the last two months that a supplementary report was necessary to bring the history of the movement down to the present time and to provide for its further extension. The Conference of State and Provincial Boards of Health of North America had unanimously recommended its adoption at the meeting held last month at Detroit, and no less than twelve American States had formally adopted it since the beginning of the present year; besides which, several others were waiting only for the action of the association. The formulation of a plan of international union of the countries using this system, whereby revisions could be made when necessary, occupied a considerable part of the report. The necessity for immediate action was strongly urged, in order that the revised classification might be available for use in 1900. The committee gave a practical example of the celerity which they recommended, stating that the plan of revision proposed, which was not drafted until after the conference of the boards of health at Detroit, had already been submitted to the highest statistical authorities of France and their cordial approval and the promised co-operation of the French statistical service obtained. Correspondence, the report said, was being conducted with the registration offices of Europe and South America, and arrangements had been made to announce the results of the revision at the session of the International Congress of Hygiene and Demography at Paris in 1900. The plan provided for consultation of pathologists, sanitarians, and all persons making use of mortality statistics, as well as the registration offices, and the decision as to changes from the present form was to be determined by ballot of the registrars actually engaged in the preparation of such reports.

The system of classification and plan of revision were adopted by the association, and the members of the national commissions for the countries represented were appointed as follows: Canada—Drs. Peter H. Bryce, E. Pelletier, and E. P. Lachapelle. Mexico—Drs. E. Licéaga, J. E. Monjaras, and J. Ramirez. United States—Drs. S. W. Abbott, A. G. Young, and C. L. Wilbur.

Leprosy Asylums.—Dr. J. Ramirez, of Mexico, read a paper on this subject. He said that in the greater part of America leprosy had gradually disappeared, although it had left extensive foci, one in Colombia and the other in Brazil. The disease was rarely found in Canada, although well-established cases had been seen. In the United States there were still a few small foci, which were found especially in Louisiana, Texas, California, Minnesota, Oregon, etc.; but the recent annexation of the Sandwich Islands placed vaccination in an especial condition at once to undertake measures of defence against that immense focus of leprosy, which was so well known and dangerous. He recommended a full investigation of the lepers of North America.

Leprosy in Minnesota.—A paper on this subject was read by Dr. H. M. Bracken, of Minneapolis. He said that the State board of health of Minnesota had knowledge of 51 lepers having resided in that State. Of these 17 had died before 1890. Of the 34 added to the records since 1890, 18 were first reported upon in 1891; 2 in 1892; 3 in 1893; 2 in 1894; 2 in 1897; and 7 in 1898 to date, September 15th. Little was known of the nationality of the 17 who died before 1890, but from various reports he said it was safe to presume that they were all from Norway. Of the late 34 cases, 29 were probably from Norway and 5 from Sweden. Of the 5 from Sweden, 1 was reported first in 1894; the other 4 in 1898. Of the 13 lepers found to be living, he could give but an outline of the present condition of only 6. He drew attention to the following facts as emphasized by the records: (1) The impression that leprosy immigrants from the Scandinavian peninsula were all from Norway was a wrong one, as five of eleven cases of leprosy placed on file by the board during 1897 and 1898 were from Sweden. (2) The feeling that physicians could quarantine against lepers by watching immigrants was an unsafe one. The family history of all immigrants from the country where leprosy prevails should be secured before they are allowed to embark for America, and no member of a leprous family should be permitted to land on our shores. (3) It would appear that the conditions antagonistic to the spread of leprosy in Minnesota were also opposed to sterility, as

borne out by the families of several lepers. Some of these had children, as was shown by the following figures: 5, 5, 6, 6, 4, 6, 4, 5, and 8. (4) It was quite possible for leprosy to die out in certain favored sections of the country, such as Minnesota, without segregation, provided the importation of lepers was discontinued. (5) Even in Minnesota, one had but to visit some of these lepers to feel that segregation should be insisted upon in all cases. One could but feel, on entering a filthy home and seeing a leprous mother careless in her habits, that the children were not safe. (6) Segregation in single States was not practicable. It would tend simply to drive lepers from States enforcing such a practice to those that were not carrying out the system. (7) A federal home should be provided for these unfortunates. They could thus be cared for more economically and more satisfactorily than through any State provision. (8) In spite of all precautions taken, there would be some leprous individuals in this part of the world for many years to come. The Scandinavian peninsula did not furnish all leprous individuals found in the United States. Great care must be exercised in dealing with lepers in the future. That we had been constantly importing this disease was a recognized fact, and also that the chances of importing it would probably be increased rather than decreased unless great care was taken in dealing with infected countries. All the lepers that came to America did not settle in the Northwestern States, and all sections of the country might not be so fortunate in affording such poor soil for the spread of the disease as did Minnesota. It was altogether probable that there were some lepers in Minnesota not registered by the State board of health.

Public Sanitation.—Mr. J. W. Hughes, of Montreal, read the report of the committee on sanitation, with special reference to drainage, plumbing, and ventilation of public and private buildings. He spoke of an increased interest in all matters relating to practical sanitation. The untiring efforts of individual sanitarians in the past had resulted in awakening active inquiry and interest. Private and public sewers were to-day better constructed and more carefully planned than in the past; but the question of the best method for the disposal of sewage had yet to be solved, and was becoming of more pressing importance every day. The question of effective and economical ventilation of dwellings was one presenting many difficulties.

Prof. S. H. Woodbridge, of Boston, dealt with the heating and ventilation of railway cars in a very exhaustive and elaborate report.

Dr. G. Mendizabal, of Mexico, spoke of the diseases of the skin and of the hairy scalp commonly transmitted by contagion at schools, and pointed out the ways of preventing them.

Following Dr. Mendizabal's paper, there came a symposium on disinfection and disinfectants, the conditions of greatest efficiency of some common disinfectants, methods of testing and using them in cities, hospitals, and in quarantine work.

Flies from a Hygienic Standpoint.—Two papers were presented on this subject. Abundant evidence was adduced to show that diptera were active agents in the spread of epidemics and of contagion. It is well known that flies transmit the germs that produce acetic fermentation in alcoholic liquors. They are also known to be important factors in causing the spread of typhoid fever and dysenteric diseases.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. George H. Rohé, of Sykesville, Md.; *First Vice-President*, Dr. Henry Mitchell, of Asbury Park, N. J.; *Second Vice-President*, Dr. J. E. Monjaras, of San Luis Potosi, Mexico; *Secretary*, Dr. C. O. Probst, Columbus, Ohio; *Treasurer*, Dr. Henry D. Holton, of Brattleboro, Vt.

Minneapolis was selected as the place for holding the next meeting, in November, 1899.

NEW YORK ACADEMY OF MEDICINE.

General Meeting, October 6, 1898.

Edward G. Janeway, M.D., President.

Surgery in the Recent War.—Maj. William Duffield Bell, surgeon of the seventy-first New York volunteers, read a paper on this topic. He said that there was but one field hospital in Cuba, which was maintained chiefly through the efforts of Major Wood. This officer loaded his own horse, and those of the medical officers with him, as well as the three ambulances, with the necessary supplies, and by repeated trips moved his hospital from Siboney to Savilla. On June 30th he established his hospital about three miles distant from the San Juan hills, and near a plentiful supply of water. There were three tents for hospital purposes. One tent was devoted to the preparation of antiseptic solutions, and contained, among other things, a large filter, through which all the water used in operations and in dressings was passed. Another tent contained surgical supplies and dressings only, and the third was used for the officers and for the especially serious cases. Although the hospital accommodations were for only one hundred, over six hundred and fifty were attended to the first day, and upward of four hundred more before the night of July 2d. There was no scarcity of dressing-materials at this hospital. The hospital staff consisted of five surgeons, several hospital stewards, and a hospital company selected from the various regiments. Three ambulances and one or two wagons completed the outfit. Shortly after nine o'clock on the morning of July 1st, the wounded began to arrive, and for the next two days there was a constant stream of wounded men coming from all directions to this one place. Toward night, five additional surgeons were called in from the firing-line to assist in the hospital, but in spite of this addition to the working-force some men lay on the ground unattended for a period of from twelve to twenty-four hours. There was an insufficient supply of clothing, due to defective transportation facilities. The transportation of the wounded was a source of anxiety to the surgeons. Men with desperate wounds had to walk or crawl distances of from one mile to several miles over a wild and rugged country. Men who had been shot through the abdomen by the Mauser bullet were known to have walked for three or four miles, and to arrive at the hospital in excellent condition and eventually recover without operation. Dr. Bell said that to his own knowledge men had been wounded in the liver and kidney, and yet up to the present time there had been no serious consequences.

The Mauser Bullet.—At a greater range than two hundred yards the Mauser bullet gave a small wound of entrance, and only a slightly larger wound of exit. If the bone was shot through at shorter range, there was always some comminution. In several instances the Mauser bullet passed through the skull and out again without producing any apparent injury to the brain, and the men returned to duty in two or three days.

The Spanish Explosive Bullets.—The explosive bullets used by the Spanish consisted of a brass coating containing soft lead. On impact, this bullet exploded and produced a ghastly wound. It was used by the Spanish volunteers, who fired it from the old

Springfield rifle. Its passage through the air was accompanied by a peculiar humming sound, and there was a short, sharp pop as it exploded. Although the use of these bullets had been denied, there were now so many observations regarding wounds produced by them that there could no longer be any room for doubt on this point.

Dressings and Wounds.—The simplest antiseptics were found to answer best. The use of iodoform was almost abandoned, because in the tropics it was apt to cause undue irritation of the skin, and was prone to be absorbed in dangerous quantities. Laparotomies were resorted to in several cases, and nearly invariably with a fatal result. The first-aid packets rendered valuable service, but the volunteers were not well supplied with them, and did not appreciate their value, so that they often threw them away. Several cases of bad compound fractures of the thigh were received at the field hospital and were dressed with careful antiseptic precautions and put up in plaster of Paris. These wounded were sent to the transports.

The Mortality.—In this campaign there were two hundred and eighty killed and four hundred wounded; but only sixty-five of the wounded died of their injuries, and but a small number had required additional care since their return to the United States.

The Surgeons a Mark for the Enemy.—The medical officers were continually exposed to the bullets of the enemy in front, and still more to the fire of sharpshooters in the rear, to whom the red cross was ever a tempting mark.

Features of Some of the Wounds.—Dr. Joseph D. Bryant inquired as to the characteristics presented by the hard and soft parts of gunshot wounds produced by the Mauser bullet. He said that he had himself seen one instance in which a Mauser ball had passed through the upper third of the humerus and out posteriorly through the soft parts of the chest wall. This man had come under his observation about four weeks after the injury. At that time the wound in the bone had closed without the discharge of fragments of any kind. There was much thickening about the parts, suggesting a condition best described as "pulverization." There was enough union to obscure any crepitus. The wound of the soft parts behind the humerus and in the thorax had not healed. This wound looked to him as if it had been made by a red-hot iron. The patient made a prompt recovery. Another case seen by him was that of a lieutenant who was one of the first wounded, and consequently received early attention from the surgeons. The ball passed through the upper third of the femur, and the limb was found to be one and one-fourth inches shorter than its fellow. Four weeks after the receipt of the injury there was an evident false point of motion. The officer stated that there had been but little hemorrhage and that the wound had healed promptly. The limb was kept in plaster of Paris for several weeks. On removal of the plaster no false point of motion was detected, but shortly afterward the man complained of pain, and examination showed the presence of such a point.

Slight Injuries to Large Blood-Vessels.—Major Bell said, regarding the injury to the soft parts, that in eight instances wounds had been received over the femoral artery, in such a situation that it would seem as if the bullet must have passed through that artery. In some of the cases all that could be detected was an aneurismal varix. Although almost incredible, it seemed that the vessels had receded from the bullet. In nearly every instance that he had seen the soft parts had healed very promptly—usually in three or four days.

Effect of Distance on the Bone Injuries.—If the wound were received within five hundred yards, the class of fractures was entirely different from those received within eight hundred yards. Nearly all the wounds at El Caney were from bullets fired at a distance of five hundred yards, whereas at San Juan most of the injuries were received at eight hundred yards or more. The bone injuries on the former battlefield were characterized by a great deal of comminution, while at San Juan there were numerous instances in which the ball passed through the long bones without producing splintering. It was here that the man was shot through the posterior portion of the skull without receiving any obvious injury of the brain.

Effect of the Krag-Jorgensen Bullet.—The Krag-Jorgensen bullet at short range was found to be explosive, like the Mauser bullet, but the range of the former was shorter by three or four hundred yards. On the visit of the British consul to the American lines, during the cessation of hostilities, he was asked to notify the Spaniards that if they did not stop using explosive bullets the Americans would retaliate in kind. To this the Spaniards replied that the Americans were also using them, and upon investigation it was discovered that the Krag-Jorgensen bullet acted in this manner.

Dr. A. M. Lessèr said that he had had under his care one hundred and eighty-one American and forty-eight Spanish soldiers. Of the one hundred and eighty-one patients, seventy-one required more or less surgical interference; the others had clean wounds. There were eighteen cases of wounds through the skull. In one of these the bullet passed through the parietal bones and fractured everything above. The patient bled profusely, and on reaching the Siboney hospital was paralyzed in both upper and lower extremities. After being trephined, he was able to move his legs and arms, indicating that the paralysis was chiefly due to the pressure produced by the blood. The man had afterward been operated upon by Dr. Abbe, for a fungous growth, but had succumbed. Another interesting case was that of Colonel Mills. A bullet entered a little below the right eye, and escaped through the left cheek. He was blind when seen. The wounds were cleansed and ice was applied to the eye. He was now able to see out of the right eye, but was blind in the left eye, although it had not been necessary to extirpate the latter. The paralysis of the muscles around the eye had disappeared, so that he had perfect control over the eyes. None of the wounds of the thorax that the speaker had seen had required interference, nothing more than plaster being needed after three or four days. He knew of two or three cases in which soldiers had been shot through the neck and clean wounds left, which had given no special trouble. The compound, comminuted fractures had done remarkably well.

The Spanish Wounded did Badly.—In the fourteen hundred and fifteen cases treated at Siboney, there were only four deaths up to the 7th of July. Traumatic fever was almost unknown in the camp. It was quite different with the Spanish soldiers. Those who received wounds in the naval battle did badly. There were no clean wounds here, so that amputations instead of resections were demanded. He had been struck by the fact that all the wounded Spanish soldiers coming under his observation had been injured by more than one American bullet. The Spanish soldiers did not have the antiseptic pads, as did our own soldiers. He was convinced that the lives of hundreds had been spared by the use of these pads. Dr. Lessèr added that he had gone to the war with the expectation of seeing considerable abdominal surgery, yet the fact remained that he had not seen a single abdomen opened, or one which seemed to need to be opened.

Immunity from Tetanus.—Dr. Janeway said that medical students had often told him that idio-

pathic tetanus was very common in Cuba, and he was therefore curious to know if tetanus had been common in the experience of the army surgeons.

Dr. Bell replied that he had not seen a single case of tetanus, and knew of only one case that had been reported, and that had occurred at Miami, Fla. Possibly this immunity was largely due to the great care taken to carry out the principles of aseptic surgery.

Maj. Daniel Mitchell Appel said that he was in charge of the sick and wounded in New York City, and had seen most of the cases referred to by Dr. Lesser. When Colonel Mills left the eye hospital, his vision was $\frac{2}{200}$ in the left eye and $\frac{3}{200}$ in the right. At first he had been totally blind. All the wounded in the hospitals here had done beautifully. Three or four cases had been subjected to laparotomy, and all had proved fatal. In these cases there was considerable laceration, not only of the intestine but also of the liver.

Therapeutic Hints.

Diarrhœa.—

℞ Tincture opium ..... 15 c.c.
Tincture rhubarb ..... 15 "
Oil sassafras ..... ½ "
Tincture catechu co ..... 30 "
Tincture lavender co ..... to make 120 "
S. Teaspoonful every three hours.

—Loomis.

℞ Tincture opium ..... 30 c.c.
Tincture capsicum ..... 30 "
Spirit camphor ..... 30 "
Purified chloroform ..... 12 "
Alcohol ..... to make 150 "
S. Teaspoonful t.i.d.

—Squibb.

Cholera Morbus.—

℞ Tincture opium ..... 15 c.c.
Tincture camphor ..... 15 "
Spirit peppermint ..... 90 "
Tincture ginger ..... 90 "
Tincture capsicum ..... 15 "
Hoffman's anodyne ..... 15 "
Dose, teaspoonful after each movement, in sweetened water.

—Dunlap.

Tetany of Gastro-Intestinal Origin in Children.—

℞ Bismuth salicylate ..... 60 gm.
Benzonaphthol ..... 80 "
Sugar ..... q.s.
Mix and divide into twelve powders. Give four powders daily.

℞ Potassium bromide ..... 3 gm.
Chloral hydrate ..... 1 "
Distilled water ..... 100 "
Syrup of bitter-orange peel ..... 50 "
M. Three tablespoonfuls daily for a child between two and three years of age.

—Tordeus, *New York Lancet.*

In Chronic Arteritis (Arterio-Sclerosis).—

℞ Infus. herb. thymi 1–200
Adde:
Extr. aquos. convall. majalis 10
Syr. aurant. cort 90
M. S. Fifty grams to be given in two doses, to be continued for five or ten days.

—Paul.

Whooping-Cough.—

℞ Bromoform ..... gtt. xlviij.
Ol. amygd. dulc 20
Gummi tragacanth 2
Gummi arabici 4
Aq. laurocerasi 4
Aq. destill 12
M. One-half teaspoonful of this mixture contains about two drops of bromoform. Give two or four drops in divided doses daily; increase to eight or more.

—Radias.

Delirium Tremens.—

℞ Potass. bromidi ..... ʒ i.
Chloralis ..... ʒ iv.
Tinct. digitalis,
Tinct. capsici,
Tinct. zingiberis,
Spir. ammon. aromat.,
Syr. aurant. cort ..... āā ʒ i.
Aquæ ..... q.s. ad ℥ viij.
M. S. A tablespoonful.

—*Bellevue Hospital.*

In Oxalaturia, improperly called phosphaturia, because of the excessive precipitation of phosphates, the following is very valuable:

℞ Strychninæ sulph ..... gr. ss.
Acidi phosphor. dil ..... ʒ i.
Extr. cocæ fld ..... q.s. ad ℥ iij.
M. S. ʒ i. t.i.d.

—H. M. Christian, *Ther. Gazette,* August 15th.

In Sexual Neurasthenia.—

℞ Acidi nitromuriatici ..... ʒ iss.
Tinct. nucis vomicæ ..... ℥ ss.
Elix. cinchonæ ..... ʒ viij.
M. S. ʒ ss. in water.

—H. M. Christian.

In Migraine Associated with Gout or Rheumatism.—

℞ Quininæ valerianatis ..... gr. xv.
Extr. colchici ..... gr. iv.
Extr. digitalis ..... gr. iv.
Extr. aconiti ..... gr. ij.
M. ft. pil. No. x. S. One at night after dinner.

—Hirtz.

To Abort Erysipelas.—

℞ Iodol 10
Collodion 100
M. S. Paint affected area and for one inch beyond with heavy coat of collodion.

—*Bulletin Général de Thérapeutique,* 1898.

Treatment of Whooping-Cough.—For a child one year old, tincture of belladonna, ʒ i. One drop every eight hours, increasing one drop each day till the tenth day. Label bottle "No. 1." Also:

℞ Potass. bromidi ..... ʒ ij.
Phenacetin ..... gr. x.
Mucilaginis acaciæ,
Aquæ puræ ..... āā ʒ i.
M. ft. sol. S. Teaspoonful every three hours during the night. Label bottle No. 2.

—R. B. Gilbert, *The Amer. Pract. and News,* No. 14, 1898.

In Amenorrhœa.—

℞ Apiol. crystallis 20
Olei steril ..... q.s. ad 100
S. One to two syringefuls daily.

—Roussel.

In Liver Disorders of Malarial Origin.—

℞ Strychninæ arsenatis 0.3
Aq. sterilisat ..... q.s. ad 100
S. Inject one syringeful every second day.

Alternate with:

℞ Quininæ lactat 20
Antipyrin 20
Aq. sterilis ..... q.s. ad 100
S. One syringeful injected every second day.

—Roussel.

In Cerebral Apoplexy.—

℞ Ergotini 0.05
Acidi lactici 10
Aq. sterilis ..... q.s. ad 100
S. Inject one to two syringefuls.

—Huchard.

Vehicle for the Iodides.—Coffee is an excellent vehicle for the administration of the iodides of potassium and sodium.

In Acute Laryngitis.—

℞ Picis liquidæ ..... ʒ i.
Alcoholis ..... ʒ iv.
M. S. ʒ i. on sponge through which steam is passed. For inhalation.

Or—

℞ Morphinæ sulph ..... gr. i.
Ext. hyoscyam ..... gr. v.
Glycerini,
Alcoholis ..... āā ʒ iv.
M. S. ʒ ss. on sponge. Inhale.

In Chronic Laryngitis and Bronchial Catarrh.—

℞ Pulv. camphoræ ..... ʒ iij.
Menthol ..... ʒ iv.
Ol. pini sylvestri ..... ʒ iv.
Ol. picis ..... ʒ ij.
M. S. Gtt. ii.–x. For inhalation.

Or—

℞ Thymol ..... gr. xv.
Eucalyptol ..... gr. xx.
Creosoti ..... ʒ ij.
Ol. pini sylvestri ..... ʒ iv.
Ol. gaultheriæ ..... ʒ i.
M. S. Gtt. ii.–v. For inhalation.

—C. C. Rice.

Palpitation of the Heart.—In palpitation resulting from beginning aortitis, acute endocarditis, pericarditis, or mitral insufficiency the following has proved serviceable:

℞ Quininæ hydrobrom. ..... ʒ i.
Digitalis pulv ..... gr. xxx.
Extr. convallariæ ..... gr. xxx.
M. ft. pil. No. xxx. S. Two to four pills daily.

—Huchard.

In Dysuria Due to Uric Acid.—

℞ Acidi benzoici,
Sodii boratis ..... āā gr. v.
Aquæ ..... ʒ i.
M. S. At dose every two hours.

—*Canada Lancet.*

Local Treatment of Neuralgia.—

℞ Menthol,
Guaiacol ..... āā 1
Alcohol absol 18
M. S. Apply twice daily on cotton.

—*Ther. Monatsschrift.*

Spermatorrhœa.—When due to spasm of the seminal vesicles:

℞ Extr. belladonnæ,
Pulv. belladonnæ ..... āā gr. iij.
Confect. rosæ ..... q.s.
M. ft. pil. No. x. S. From one to three pills at bedtime.

Or, instead, pulv. camphoræ, gr. ¾, or lupulini, gr. iss., may be given; or potassium bromide, gr. xv.–lx. in twenty-four hours. When the result of atony of the seminal vesicles, cold enemata are prescribed, together with cold jet douche of twenty seconds' duration, and the following powder is given morning and night:

℞ Pulv. ergotæ ..... gr. iss.
Pulv. nucis vomicæ ..... gr. iij.–x.
M. S. For one dose.

—Sinéty, *Jour. de Méd. de Paris.*

Mental Strain.—The only rational treatment is to remove the cause. Where this is impossible, in addition to hydrotherapy and massage give pil. strychninæ arsenatis, 0.001 mgm. at a dose twice daily, and one of the following pills at breakfast or dinner:

℞ Zinci phosphid ..... 0.80 cgm.
Pulv. gum. arabic ..... 1 gm.
Pulv. glycyrrhizæ ..... 3 gm.
Mellis ..... q.s.
M. ft. pil. No. 100. Coat with silver and keep dry in dark bottle.

This can be kept up for a long while, but if strain is continuous it is best after a time to give the strychnine pill every second day and the zinc pill every fourth day.—Romme, *Presse Méd.*

Epilepsy.—

℞ Potassii iodidi ..... ʒ i.
Potassii bromidi ..... ʒ ij.
Ammonii bromidi ..... ʒ iiss.
Potassii bicarbonatis ..... gr. xl.
Infus. calumbæ ..... q.s. ad ʒ vi.
M. S. A teaspoonful before each meal, and three teaspoonfuls at bedtime, with a little water.

—Brown-Séquard.

Sciatica.—

℞ Spirit of glonoin ..... 5 gm.
Tincture of capsicum ..... 7.5 "
Peppermint water ..... 15 "
M. S. Five to ten drops, three times a day.

—P. M. Mikhalkine.

Simple Bitters.—One may indeed accept it as true that these substances exert a special influence on certain nervous elements which are in the walls of the stomach, and are concerned in the process of nutrition—an influence similar to that which they exert on the nerves of taste. Nevertheless, at present there is not a single genuine (experimental) proof to justify such a belief. Not one of these bitters has any special advantage as compared with the rest. Some physicians will prefer one, and others will prefer another. —Schmiedeberg.

"Chelsea Pensioner" for Rheumatism.—

℞ Powdered guaiacum ..... ʒ i.
Powdered rhubarb ..... ʒ ij.
Bitartrate of potassium ..... ʒ i.
Sublimed sulphur ..... ʒ i.
Powdered nutmeg ..... ʒ ss.
Honey ..... 1 lb.
Mix thoroughly. S. Two large tablespoonfuls to be taken night and morning.

"Lady Webster's Dinner Pill."—

℞ Powdered Socotrine aloes ..... gr. ij.
Powdered mastich ..... gr. ss.
Powdered red rose leaves ..... gr. ss.

Neuralgia.—

℞ Chloral,
Menthol,
Thymol ..... āā 1 part.
Camphor ..... 3 parts.
M. S. Apply locally.

Treatment of Syphilis.—Dr. W. C. Heggie (*The Dominion Medical Monthly and Ontario Medical Journal*, April) writes: "My experience in treating some four hundred syphilitics during the past two years has been that in the true syphilitic stage mercury is the remedy *par excellence*. In the sequelæ potassium iodide stands without a rival. Of all the preparations of mercury the bichloride easily takes the lead, especially immediately after infection. I usually begin treatment with one grain of calomel every hour till the bowels are thoroughly flushed; then put the patient on—

℞ Hydrarg. bichlor. ..... gr. $\frac{1}{16}$–$\frac{1}{4}$
Nucis vomicæ ..... ♏ x.
Ext. phytolaccæ dec. ..... ♏ ij.
Aquæ ..... q.s. ad ʒ ij.
M. To be taken four times daily.

I begin with one-sixteenth grain of bichloride and increase the dose till I get an apparent effect. I am not afraid of salivation; in fact, continue the remedy until mercurialization begins to develop, when the remedy is stopped and the patient put for a week or more on the vegetable alteratives. The emunctories should be kept open and a hot bath given twice a week. Any complications should be treated in conjunction with the antisyphilitic treatment, which should be continued for at least six months after all symptoms disappear."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE WEATHER AND THE PUBLIC HEALTH—THE DROUGHT—SCHOOL INFECTIONS—ASYLUMS BOARD—LIVERPOOL'S NEW LABORATORIES—PROPOSAL FOR A LONDON LABORATORY—NOTIFICATION—VACCINATION STATIONS—HOSPITAL STAMPS.

LONDON, September 23, 1898.

THE weather is still uppermost in our thoughts. The heat wave has, indeed, passed, but its influence seems to remain. Some intervals of rather sharp cold have told us that autumn is certainly here, and yet most of the days have been sunny and warm and we talk of Indian summer.

The public health has continued good, and although in parts there has been an increase of diarrhœa it is not more marked than in other warm seasons.

Even the water famine at the East End has not yet produced much effect on the mortality returns, though, no doubt, it has increased the amount of sickness among the poorer inhabitants. A connection has been made with two other companies and thus a considerable increase in the amount of water supplied has been effected, and it is believed that in a few days this increase will be greater. The agitation against the company which has failed to fulfil its contract naturally continues, and it is to be hoped that this time it will lead to legislation. The president of the local government board has incurred much unpopularity by his supineness and later by his attempt to absolve the company. The fact that other companies have a surplus is regarded as a most forcible argument in favor of making all of them intercommunicate and some day placing all under one authority. The county council has a better chance than ever of securing the control.

The prolonged dry summer has had a perceptible effect in various parts of the country, and many district health authorities have been considering what might be the consequence of a longer period of absence of rainfall. Most of the rivers are flowing at a much lower level than has occurred for many years, and in some places the drains are not properly flushed, while wells are becoming dry. Even Loch Katrine, which supplies Glasgow, is ten inches lower than it has been seen for nearly twenty years. There is no fear of this failing, but the corporation is engaged on works which will secure an abundant increase over what has sufficed for the last forty years, and so provide for all possible increase of population and maintain Glasgow's place as the best-supplied city.

The effect of schools in spreading diphtheria has long occupied the attention of sanitarians. The medical officer of the school board seems to attach little importance to this influence, but it is so natural to believe that the aggregation of many children offers full opportunity for the spread of so infectious a disease, that no one can be surprised that the danger is frequently pointed out. There have been many outbreaks which have been traced to the presence of a case or two in a school, and the closing of such an infected school has often sufficed to arrest the spread.

At Southall, Dr. Windle suggested to the authorities systematic examination of the school children, and they accepted his advice. They had previously adopted the plan with great success in the case of scarlet fever, and there can be little doubt that the inspection which has just been carried out will serve to check diphtheria, which has prevailed for the last two years in Southall. The local authorities there deserve credit for what seems to be a new departure, and Dr. Windle is to be congratulated on finding them ready listeners to his excellent suggestions.

The excessive expenditure of the asylums board, on which I have more than once remarked, is receiving attention. The local government board has directed its chief inspector to inquire into the excessive cost of the Brook Hospital, the architect's responsibility, and what supervision was exercised by the managers or the committee.

Liverpool is expecting to have a most brilliant celebration of the opening of the new laboratories of physiology and pathology at University College. Lord Lister is to conduct the ceremony and to receive another honorary degree, and of course the lord mayor will give a banquet on the occasion.

There is a prospect of a bacteriological laboratory being established for London, on a scale worthy of the metropolis. Some of the district authorities have made representations on the subject to the County Council, and it is anticipated that others will follow. The matter will probably come before the council in November.

Notification has often enough been opposed as likely to be extended to an egregious extent. Many would like to see tuberculosis included in the list of compulsorily notifiable diseases, and more still think measles ought to be. The difficulties in each case have so far restrained the zeal of the sanitarians and have even greatly added to the opposition. It has sometimes been said that health officers will not be satisfied until they get returns of every case of gonorrhœa or syphilis. I hear that the Germans contemplate such an extension and that in some places it has been inaugurated. I hardly expect it will become general in Germany, and am pretty sure John Bull will not follow the example.

The local government board has informed the boards of guardians that in future vaccination stations will be abandoned, in view of the arrangements provided for domiciliary vaccination by the new act.

Four new stamps have been issued on behalf of the Prince of Wales' hospital fund. They are for 1*s.*, 2*s.* 6*d.*, 5*s.*, and 10*s.* respectively, and offer an easy way of subscribing to the fund.

OUR PARIS LETTER.

(From our Special Correspondent.)

LIGHT AND HYGIENE FOR CHILDREN—MORTALITY RATE FROM TUBERCULOSIS LARGELY INCREASED BY THEIR LIVING IN DARK ROOMS WITHOUT SUN EXPOSURE—FRENCH SOLICITUDE FOR YOUNG CHILDREN—CONDURANGO IN THE TREATMENT OF STOMACHAL DISEASES—THE BACTERIOLOGICAL LABORATORY, ETC.

PARIS, October 1, 1898.

A QUESTION of hygiene, or rather an important hygienic point and one often overlooked altogether in the selection of sleeping-rooms for young children, is that of light—the light of the sun shining directly into the rooms, and not the reflected light of wall or reflector. That is the kind of light that accompanies dampness and fosters depression and melancholia. And if such quarters are bad for those of maturer years, how much worse are they for children! To place a child in a back-room, where the sun never shines, is to predispose it to rachitism, pallor, anæmia, and neurasthenia. It is preparing the ground for phthisis to deprive children of the rays of the sun, with their triple qualities—calorific, luminous, and chemical—which are indispensable to life and health. One of the most fruitful causes of the frightful mortality from tuberculosis in Paris—eleven thousand in an annual total of fifty thousand — is by living in rooms of this kind, overlooking dark and cold

courts or yards, or occupying back shop rooms, often overcrowded and lighted by transoms or getting their obscure light from other rooms. The light of the sun alone is not only a powerful source of vitality, but it actuates the cells of our brains, invigorates our muscles, heightens our tonus, increases the pressure of the blood in our arteries, and gives us as a consequence that feeling of well being, that lightness of body and step, that tendency to take things and see them at their best, that characterize perfect health.

It is often enough to take a debilitated, anæmic child, who has been living in an obscure room such as mentioned above, and place it in a bright, sunlit room of good size, to observe an immediate improvement without the administration of medicine. The subject of infantile hygiene is one of great importance, and it is interesting to note in this connection a study that has just been made by Dr. Maurice de Fleury, with reference to the number of hours daily to be allowed young children for the reparation of their strength by sleep. Dr. de Fleury, inspired by the law that the newborn babe sleeps almost constantly and the old man very little, has established a schedule, decreasing as the children advance toward adult life.

For instance, a child of from five to eight years of age ought to sleep from eight o'clock in the evening to seven in the morning—that is, eleven hours; a child of from eight to twelve years of age should sleep from nine in the evening to seven in the morning—or ten hours; a child of from twelve to fifteen years of age, from half-past nine in the evening to half-past six in the morning—or nine hours. Later it is well to accustom them to seven hours' sleep, but this should be done gradually; first dropping to eight hours, and then in six months to seven hours. These are general rules for children in ordinary health; there are, however, others for whom it is advisable to increase the hours of sleep. Sickly, thin, enervated, and excitable children are the better for half an hour or an hour's sleep after the midday meal.

The medical profession and the laity are just now giving much attention to infantile hygiene and medicine; in the discussions and writings on the subject nutrition and nourishment play an important rôle, and the French seem to be awakening to the fact that healthy children mean healthy men and, what is very much to the point to-day, more soldiers—an army stronger mentally as well as physically, and one better able to withstand the fatigues of military life in time of peace and its hardships and privations in time of war.

Professor Lemoine has just related several cases of diseases of the stomach relieved by the administration of condurango. Our American confrères remember the history of condurango in the treatment of cancer, but it is not as a cure for cancer that the remedy is advised, but simply to allay pain in a variety of stomachal affections, including the pains of carcinoma. Condurango facilitates alimentation and improves nutrition in those patients suffering from the stomach; moreover, it may prevent cachexia. A favorite preparation is condurango in powder form given in wafers, from two to four grams a day, in broken doses. Professor Lemoine orders in his service and practice pills of ten centigrams of the powder of condurango made up with any excipient; his patients take from five to eight of them a day. It is given in cases of atonic dyspepsia, stomachal dilatation, chronic gastritis, stomachal catarrh, and gastralgia, principally to allay pain. This is certainly a new way to use an old drug, and, judging by Professor Lemoine's experience, condurango powder must be a very efficacious remedy in a variety of stomachal diseases.

At a recent meeting of the Société de Thérapeutique, attention was called to the substitution of the essence of wintergreen for the salicylate of sodium and the employment of salicylate of sodium insisted upon. The essence of wintergreen, it was pointed out, has an irritating action on the epidermis and epithelium, and its composition is unreliable. This accounts for the fact that some practitioners who employ the essence of wintergreen in the treatment of articular rheumatism have had negative results.

Good work is being done by the municipal bacteriological laboratory. This laboratory for the diagnosis of contagious affections was created by the municipal council in 1895, and is open to the public every day in the year from eight o'clock in the morning until eight in the evening, including Sundays and holidays; moreover, the necessary articles are given to doctors who ask for them for the bacteriological diagnosis of diphtheria, tuberculosis, and contagious affections of which the germs are known. The results of the analyses are sent directly to the doctors, at longest twenty-four hours after reception of the pathogenic products at the laboratory. These results can be sent by telegraph if desired and at the expense of the doctor, but the examination and diagnosis are absolutely gratis. The laboratory received, in August, 1898, forty-eight products suspected to be tuberculous, in which the bacillus of Koch was discovered sixteen times.

"A BRIDLE FOR THE CONTROL OF MOUTH BREATHING."

To the Editor of the Medical Record.

Sir: The Medical Record of September 10, 1898, contained an illustrated article, "A Bridle for the Control of Mouth Breathing." In the issue of the Medical Record of September 24, 1898, a criticism of this article appeared over the signature of W. Freudenthal, M.D., of New York City, who manifestly either "studied the pictures" without reading the descriptive matter, or read the latter without an intelligent comprehension of its import.

Noreurne B. Jenkins, M.D.

Knoxville, Tenn.

A SAFE AND SIMPLE METHOD OF VACCINATING.

To the Editor of the Medical Record.

Sir: I am informed that the method of vaccinating by use of the knife is yet practised by many boards of health, and at dispensaries and similar institutions, where it frequently happens that a large number of people are to be vaccinated at one time.
